Plesiomonas shigelloides

Shai Ashkenazi

Plesiomonas shigelloides is a common inhabitant of surface water and fish. It causes acute gastroenteritis, mainly in travelers to tropical regions, and uncommonly severe extraintestinal infections in children.[1–6]

Description of the Pathogen

P. shigelloides is the only species in the genus *Plesiomonas*. Based on phenotypic characteristics, *P. shigelloides* was classified in the Vibrionaceae family.[4] However, sequence analysis indicates its phylogenetic ancestry is more closely aligned with the tribe Proteaceae in the Enterobacteriaceae family.[7]

P. shigelloides are facultative anaerobic, gram-negative rods, which are motile using a polar flagellum. Some isolates of *P. shigelloides* share the capsular O antigen with that of *Shigella sonnei*. *P. shigelloides* are oxidase, indole, and catalase positive. They also are ornithine, lysine, and arginine decarboxylase positive.

P. shigelloides grow well on traditional enteric media, including MacConkey, Hektoen enteric deoxycholate citrate (Leifson), and *Salmonella-Shigella* agars. Growth is enhanced when inoculated on selective media, such as trypticase soy broth with ampicillin.[3] *P. shigelloides* produces gray, nonhemolytic colonies after 18 to 24 hours of incubation at 37°C; optimal growth occurs at temperatures of 40°C to 44°C.[3]

Pathogenesis

P. shigelloides is epidemiologically associated with gastroenteritis, particularly in the first 2 years of life. However, when fed to adult human volunteers, the bacteria does not cause diarrhea.[8,9] In vitro and in vivo studies suggest low pathogenicity.[10] Clinical manifestations of gastroenteritis suggest enteroinvasion as a possible mechanism of disease. However, *P. shigelloides* yields negative or variable results by most standard assays of invasiveness.[3,9–11] DNA probes for virulence genes of *Shigella* spp. and enteroinvasive *Escherichia coli* also are negative.[9,11]

Mutant studies have documented a crucial role of the lipopolysaccharide in pathogenicity through resistance to complement and adhesion to and invasion of some eukaryotic cells.[12] *Plesiomonas* does not produce an enterotoxin; cytotoxin production has been demonstrated in some strains.[9,11,13] A high-molecular-weight plasmid has been identified in most strains of *P. shigelloides,* but its role in the pathogenesis of diarrhea has not been determined.[10] Investigations have demonstrated pronounced cell adhesion of *P. shigelloides* clinical isolates, a characteristic not observed in environmental isolates.[14]

It is unclear whether some strains are virulent but others are nonpathogenic or whether there is age- and immunity-related susceptibility. In a case-control study of childhood diarrhea in Bangladesh, *P. shigelloides* was isolated with similar frequency from stool specimens in cases and controls, but it was not isolated in nondiarrheal patients in China.[1,15]

Epidemiology

P. shigelloides was isolated from 3% of outpatients with acute diarrhea in China and was the only pathogen isolated from 2%.[1] Its natural reservoirs are water and fish in temperate and tropical regions. Humans are infected with *P. shigelloides* after ingestion of contaminated food or water or through contact with colonized animals.[16] *Plesiomonas* colonizes the gut of various animals and has been isolated from cats, dogs, pigs, cows, snakes, newts, fish, shellfish, monkeys, and vultures; molecular studies suggest that *P. shigelloides* can be zoonotic.[17] Although *Plesiomonas* has been identified in about 1% of tropical fish tanks, aquarium-associated illness is rare.

Occupations associated with an increased risk of *P. shigelloides* infection include veterinarians, aqua culturists, fish handlers, and zoo keepers.[3] *P. shigelloides* can be isolated from stools of patients with gastroenteritis who reside in tropical and subtropical regions of Africa, Asia, and Australia.[3] Asymptomatic carriage of *P. shigelloides* in humans living in developed countries is uncommon. The organism has been isolated from coastal waters of the Gulf of Mexico and has been implicated as a cause of diarrhea in travelers to Mexico and the Caribbean. In the United States and Europe, most cases of gastroenteritis are associated with travel to tropical areas or with consumption of raw oysters or shellfish.[3]

Clinical Manifestations

After an incubation of 1 to 4 days, acute gastroenteritis is the most common clinical presentation.[1–3] About 70% of gastroenteritis due to *P. shigelloides* is associated with an underlying illness or identifiable risk factor, such as travel or consumption of raw seafood.[1,3,4] The clinical presentation varies; symptoms include abdominal cramps, dehydration, fever, headache, vomiting, and diarrhea, which usually last for a few days.[1,2] A study from Bangladesh suggests that diarrhea primarily occurs in the first 2 years of life. Most illness (84%) manifests with acute watery diarrhea, although dysenteric disease (16%) and persistent diarrhea (13%) lasting more than 2 weeks also occur. A Canadian study documented persistent symptoms (>2 weeks in 76%, >4 weeks in 32%), mostly in people who recently had traveled, been exposed to seafood, or had contact with contaminated water. However, the high frequency of persistent symptoms may reflect selection biases.

Extraintestinal manifestations are rare but include bacteremia, meningitis, osteomyelitis, septic arthritis, cellulitis, endophthalmitis, proctitis, peritonitis, pseudoappendicitis, pancreatitis, and cholecystitis.[1,2,5,6,18–23] Underlying illnesses associated with extraintestinal infections include immunodeficiency, sickle cell disease, and cirrhosis and other hepatic diseases.[1,2] *P. shigelloides* keratitis due to a laceration has been reported.[24] There are cases of early-onset neonatal septicemia and meningitis.[4,15,17] The mortality rate is high when extraintestinal infection occurs. For neonates with meningitis, the mortality rate can be greater than 80%.

Diagnosis

Isolation of the organism after growth in appropriate medium is essential for the diagnosis of *P. shigelloides.* Clinical laboratories sometimes underrecognize the organism because up to 30% of clinically significant isolates ferment lactose. If an oxidase test is not performed, these lactose-fermenting isolates can be misidentified as normal enteric flora. When *P. shigelloides* is being considered on the basis of foreign travel or ingestion of raw seafood or untreated water, an oxidase test should be performed. Selective media also can be used. *P. shigelloides* is isolated readily from normally sterile body fluids in cases of extraintestinal infection.

Treatment

Acute Gastroenteritis

Because *P. shigelloides*–associated gastroenteritis is usually self-limited, replacement of fluid and electrolyte losses is the main treatment. The need for antimicrobial therapy is controversial because the disease is usually self-limited. In some studies, antimicrobial therapy appears to shorten the duration of illness, but a case-control study of Thai children found no difference in the duration of diarrhea in treated and untreated groups.[25] Antimicrobial therapy is recommended for gastroenteritis in children with underlying conditions. *P. shigelloides* are usually resistant to penicillins (by β-lactamase production) and sometimes to trimethoprim-sulfamethoxazole, but they are usually susceptible to cephalosporins, amoxicillin-clavulanate, carbapenems, and fluoroquinolones.[1,4,26,27] When antimicrobial therapy for *Plesiomonas*-gastroenteritis is indicated, the recommended empiric agent is ceftriaxone (50 mg/kg once daily for 5 days).

Extraintestinal Infections

Intravenous antibiotic therapy is recommended for children with extraintestinal infections. It should be guided by local susceptibility data and then by the individual isolate because there is considerable variation in antimicrobial susceptibility. Empiric therapy with an extended-spectrum cephalosporin is reasonable because isolates typically are susceptible in vitro and because of good penetration into the cerebrospinal fluid.[1,4,26,27]

Key Points

Epidemiology, Clinical Manifestations, and Management of *Plesiomonas shigelloides* Infection

Epidemiology

- Natural reservoirs are fresh water and fish in temperate and tropical regions.
- Infections usually are associated with travel to tropical areas or consumption of raw seafood.

Clinical Features

- Incubation period: 1 to 4 days
- Typical illness: acute onset of diarrhea (sometimes with blood or mucus), with nausea, vomiting, abdominal cramps, and sometimes fever
- Extraintestinal manifestations: bloodstream and focal infections (rare, occurring mainly in neonates or children with chronic underlying conditions)

Management

- Mainstay is replacement of fluid and electrolyte losses, preferably by oral rehydration.

- Antimicrobial therapy is recommended for extraintestinal infections and for acute gastroenteritis in children with underlying conditions.
- Most strains produce β-lactamase, but they are susceptible to cephalosporins, amoxicillin-clavulanate, carbapenems, and fluoroquinolones.
- Recommended empiric antibiotic therapy usually is a third-generation cephalosporin.

Proteus, Providencia, and *Morganella* Species

William J. Barson, Stella Antonara

Microbiology and Epidemiology

Organisms belonging to the genera *Proteus, Providencia,* and *Morganella* are phylogenetically related members of the family Enterobacteriaceae and often referred to as the Proteeae. All members of these genera have phenylalanine deaminase activity, and most have urease activity and motility. Organisms can be isolated readily in the laboratory on enriched media, such as blood and chocolate agars, and on gram-negative selective media, such as MacConkey agar, on which they appear as colorless colonies because they do not use lactose.[1–5] Identification of these species can be successfully achieved by the use of proteomic methods such as matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometric analysis.[6]

There are at least five named *Proteus* species and several unnamed genospecies. The named species include *P. mirabilis, P. vulgaris, P. penneri, P. hauseri,* and *P. myxofaciens.* The two species of primary human clinical significance are *P. mirabilis* and *P. vulgaris.* Both species produce hydrogen sulfide and swarm on noninhibitory agar medium. *P. mirabilis* is positive for ornithine and negative for indole production, whereas *P. vulgaris* is negative for ornithine but positive for indole. *P. penneri* is a species that accommodates indole-negative, genetically distinct variants of *P. vulgaris.*

There are five named *Providencia* species, including four that produce indole: *P. stuartii, P. rettgeri, P. alcalifaciens,* and *P. rustigianii. P. stuartii* and to a lesser extent *P. rettgeri* are the two species of primary human significance. *Providencia* species can be differentiated from *Proteus* species and *M. morganii* based on their ability to use citrate as the sole carbon source and to ferment D-mannitol. *M. morganii* is the only *Morganella* species, which has subspecies *morganii* and *sibonii. M. morganii* usually is positive for indole, urea, and ornithine.[1–5]

Proteus, Providencia, and *M. morganii* are found in the natural environment in soil and water and in environmental sources in healthcare facilities. They are normal flora in the gastrointestinal tract of humans, other mammals, and birds.[1,5] These organisms can colonize the skin and respiratory mucosa of hospitalized patients and healthcare personnel and can be transmitted to other patients. Members of all three genera also commonly colonize reptiles and fish.

Investigations of pathogenic mechanisms of these organisms have focused on *P. mirabilis* as an agent of urinary tract infection (UTI). Virulence factors that appear to contribute to pathogenicity include motility, production of fimbrial proteins, and other factors that facilitate attachment to uroepithelial cells.[5] Other studies have demonstrated the ability of *Providencia* spp. to attach to and invade human cells in tissue culture and implicated these organisms as agents of gastroenteritis, including travelers' diarrhea.[5]

P. mirabilis causes most cases of infection due to members of the *Proteus, Providencia,* and *Morganella* genera and is considered primarily a community-associated pathogen. Other members of these genera often are isolated in healthcare-associated infections (HAIs), such as UTIs, burn wounds, and bloodstream infections (BSIs). *P. mirabilis* was the cause in 4% of HAIs at major centers in the National Nosocomial Infections Surveillance System from 1986 to 1989. *Proteus* spp. accounted for 3% of healthcare-associated UTI in children and frequently was associated with indwelling bladder catheters.[7] Wound infections due to *Proteus* spp. have occurred after surgical procedures (e.g., spinal fusions, myocutaneous flap surgery in patients with spinal injury), animal bites, burns, and with decubitus ulcers.[5,8–11]

Clinical Manifestations

P. mirabilis is the third most frequent agent of UTI in childhood after *Escherichia coli* and *Klebsiella* spp.[12,13] In one series of primary UTI in males, *P. mirabilis* replaced *E. coli* as the most prevalent pathogen.[14] *Proteus* spp. also frequently cause recurrent UTIs. The urease enzyme produced by *P. mirabilis* and related bacteria hydrolyzes urea in the urine, forming ammonium hydroxide. This reaction increases urinary pH, which is toxic to renal cells and promotes precipitation of inorganic and organic compounds, leading to the formation of struvite stones.[15] These stones can act as foreign bodies, rendering infections difficult to eradicate and promoting reinfection. Recovery of *Proteus* spp. from urine should alert the physician to the possibility of urolithiasis.

Toxic encephalopathy due to a high serum concentration of ammonia has been reported as a complication of *P. mirabilis* and *P. rettgeri* UTI in children with prune belly syndrome.[16,17] Xanthogranulomatous pyelonephritis, most commonly due to *E. coli* and *P. mirabilis,* is a rare type of chronic pyelonephritis that can be mistaken for Wilms tumor.[18] This diagnosis should be considered for a child with a renal mass, hematuria, anemia, and leukocytosis, and it can be associated with urinary tract obstruction and nephrolithiasis.

Proteus, Providencia, and *Morganella* spp. have been recovered from children with a variety of infections other than UTIs, including chronic suppurative otitis media.[19] *P. mirabilis* is the third most common organism recovered from cultures of ear drainage in children with tympanostomy tubes; *Pseudomonas aeruginosa* and *Staphylococcus aureus* are recovered more commonly.[20] Intracranial and extracranial complications due to *P. mirabilis* have been associated with mastoiditis and chronic otitis media.[21,22] *Proteus* spp. have been reported as a cause of folliculitis, pneumonia, BSI, sacroiliitis, and meningitis; hepatic, pulmonary, renal, and splenic abscesses; osteomyelitis in patients with sickle cell anemia; sinusitis in neurologically impaired children; soft tissue or wound infections complicating trauma, burns, surgical procedures, and skin lesions associated with Buruli ulcers, cutaneous leishmaniasis, and hidradenitis suppurativa; necrotizing fasciitis associated with omphalitis; spinal cord abscess complicating a dermal sinus; and brain abscess as a complication of neonatal meningitis and after neurosurgical procedures.[5] Many of these infections occur in neonates and immunocompromised hosts.

In a 21-year review by Unhanand and colleagues, *P. mirabilis* was the cause of gram-negative meningitis in 3 (6%) of 49 term infants and in 1 (6%) of 18 infants who were 1 to 3 months old.[23] *Proteus* spp. also have been associated with pump pocket infections in patients receiving intrathecal baclofen for spasticity.[24] Neonatal infections, including early- and late-onset septicemia, meningitis, and brain abscess, have been attributed to *M. morganii*.[5,25,26] *Proteus* spp. and *M. morganii* can secrete the enzyme L-histidine decarboxylase, which can convert the free amino acid histidine, found in muscle tissue of certain fish (e.g., tuna, mahi-mahi, bonito, mackerel, sardine), into histamine. This occurs in improperly stored fish and can lead to scombroid poisoning with an anaphylactic-like syndrome after human consumption.[5]

In Brazil, Jorge and coworkers described the microbiology of abscesses due to *Bothrops* spp. snake bites and found *M. morganii* in 23 (58%) of 40 and *P. rettgeri* in 7 (18%) of 40 abscesses; 16 (40%) of 40 cases were polymycrobial.[27] *Providencia* spp. are recovered occasionally from patients with chronic otitis media or infected burn wounds and rarely from patients with meningitis. It also can be responsible for diarrhea (especially *P. alcalifaciens*).[28–30] When recovered from the urinary tract, *Providencia* spp. typically are found in the setting of an underlying structural, physiologic, or neurologic abnormality (e.g., neurogenic bladder).[5]

Treatment

Treatment of infections due to these organisms can be difficult because of frequent antimicrobial resistance. Although most isolates of *P. mirabilis* remain susceptible to ampicillin, first-generation cephalosporins, and trimethoprim-sulfamethoxazole (TMP-SMX), plasmid-mediated resistance to penicillins and cephalosporins due to β-lactamases is becoming more common.[31,32] *P. mirabilis* is resistant intrinsically to nitrofurantoin, a characteristic useful for identification.

The indole-producing members of the Proteeae, including *Proteus vulgaris, Providencia* spp., and *M. morganii,* typically are resistant to ampicillin and cefazolin, as is the indole-negative species *Proteus penneri*. Historically, third- and fourth-generation cephalosporins, aztreonam, piperacillin-tazobactam, carbapenems, fluoroquinolones, and TMP-SMX usually were active.[5,33–35]

Worldwide, there are increasing reports of resistance to TMP-SMX and fluoroquinolones among *P. mirabilis* and *M. morganii* recovered from hospitalized patients, with resistance rates for *P. mirabilis* of 16% and 15% and for *M. morganii* of 25% and 22% to TMP-SMX and fluoroquinolones, respectively; higher resistance rates were associated with overuse of these agents.[5,35] *P. mirabilis* urine isolates from pediatric outpatients and inpatients retain similar susceptibility patterns for ampicillin, first-generation cephalosporins, and TMP-SMX.[36]

Extended-spectrum β-lactamase (ESBL)–producing strains of *P. mirabilis* and other species of the Proteeae can cause infections in children.[37–39] Healthcare-associated outbreaks have occurred due to strains of *P. mirabilis* that have acquired plasmid AmpC-type β-lactamases similar to the chromosomal AmpC enzymes found in *Enterobacter cloacae* and other Enterobacteriaceae.[40] Most isolates of *M. morganii* carry genes coding for AmpC-type β-lactamase enzymes. A neonate with early-onset *M. morganii* sepsis developed persistent ventriculitis due to emergence of a cefotaxime-resistant variant as a result of derepression of its AmpC β-lactamase.[41] Combination therapy with meropenem, ciprofloxacin, and gentamicin resulted in a microbiologic cure. Use of third-generation cephalosporins as monotherapy should be reconsidered when treating serious infections due to organisms known to harbor AmpC β-lactamases (see Chapters 138 and 140).

The activity of aminoglycosides against the Proteeae varies, with amikacin tending to have the most reliable activity. When infection with one of these organisms is suspected, initial empiric treatment regimen for serious infection should include meropenem and amikacin. For infection of the central nervous system, a minimum of 2 weeks of antibiotic therapy is recommended after documented cerebrospinal fluid (CSF) sterilization. Drainage of brain abscesses may be required, but resolution of smaller abscesses after antibiotic therapy alone has been reported. Specific therapy should be guided by the results of definitive identification and susceptibility testing (see Chapter 46).

Gram-negative bacillary otitis externa can be treated effectively with topical ofloxacin otic solution.[42,43] A 7- to 10-day course of antibiotics usually is adequate for treatment of uncomplicated UTI; removal of an indwelling urinary catheter hastens eradication. Otherwise, failure to eradicate the bacteria should alert the physician to the possibility of urolithiasis or a structural anomaly. Stone removal or surgical correction of an obstruction often is required for a cure.

Key Points

Diagnosis and Management of *Proteus, Providencia,* and *Morganella* Infections

Microbiology

- Members of the Enterobacteriaceae family; these catalase-positive, oxidase-negative, gram-negative bacilli are non–lactose fermenting on MacConkey agar.
- Grow well on blood, chocolate, and MacConkey agars
- *Proteus spp.* swarm on blood agar media.
- *Proteus mirabilis, Proteus vulgaris, Providencia stuartii, Providencia rettgeri,* and *Morganella morganii* are the species. Susceptibility testing performed by automated and manual methods is standard. Most commonly associated with human infection.

Epidemiology

- Normal enteric flora but also found in environmental soil and water
- Can be found in environmental sources of healthcare facilities

Clinical Importance

- Urinary tract infections and occasional cause of chronic ear drainage
- Secondary infections of traumatic wounds, burns, and operative sites
- Neonatal sepsis or meningitis
- *Proteus* spp. and *M. morganii* associated with scombroid fish poisoning

Treatment

- *Proteus mirabilis*: usually susceptible to ampicillin, first-generation cephalosporins, fluoroquinolones, and trimethoprim-sulfamethoxazole; resistant to nitrofurantoin
- Indole-positive Proteeae, including *P. vulgaris, Providencia spp.,* and *M. morganii* are resistant to ampicillin and first-generation cephalosporins but usually susceptible to piperacillin-tazobactam, third- and fourth-generation cephalosporins, and carbapenems.
- Empiric therapy for serious infections with carbapenem and amikacin is considered effective against extended-spectrum β-lactamase (ESBL)– and AmpC β-lactamase–producing *Proteus*; fourth-generation cephalosporin can be used to treat infection due to AmpC β-lactamase–producing organisms.
- Otitis externa usually can be treated with a topical fluoroquinolone.

Duration of Therapy

- Uncomplicated urinary tract infection (UTI): 7- to 10-day course usually adequate; removal of a catheter hastens eradication
- Central nervous system infection: minimum of 2 weeks after documented cerebrospinal fluid bacteriologic sterilization

Special Considerations

- Recovery of *P. mirabilis* from urine should alert to the possibility of urolithiasis (i.e., struvite stones).

- Hyperammonemia with encephalopathy has been reported in prune belly syndrome with *P. mirabilis* and *P. rettgeri* UTI.

Serratia Species

Eunkyung Song, Asunción Mejías, Stella Antonara

Microbiology

The genus *Serratia,* family Enterobacteriaceae, contains at least 15 species. *Serratia marcescens* is the primary pathogenic species in humans, but a few cases of human infections are caused by *S. liquefaciens*, *S. rubidaea*, *S. plymuthica*, *S. odorifera*, *S. ficaria*, and *S. fonticola*, which are diverse groups containing several biogroups based on DNA hybridization analyses.[1–4]

The facultatively anaerobic, motile, gram-negative bacilli are recovered readily in the laboratory on enriched, nonselective and selective enteric agar. Strains of *S. rubidaea*, *S. plymuthica,* and *S. marcescens* (more frequent in environmental than in hospital-acquired samples) commonly produce the red pigment prodigiosin and are red colored. Most human isolates of *Serratia* spp. do not ferment lactose (and therefore appear as colorless colonies on the enteric agars), but they reduce nitrate to nitrite, are catalase positive and cytochrome oxidase negative, and ferment glucose and a number of other sugars.[5]

S. marcescens and the other *Serratia* spp. do not produce many virulence factors. Hydrolytic enzymes, including gelatinase, lipase, and DNAse, are commonly produced, an uncommon property somewhat among the Enterobacteriaceae. These and other extracellular enzymes may be virulence factors that promote tissue invasion. The most important biochemical tests for differentiating among *Serratia* spp. are the finding of lysine and ornithine decarboxylase and acid production from several sugars.[1–4]

Epidemiology

Because *Serratia* spp. are not a common component of human fecal flora, human infections are thought to result from environmental contamination. *Serratia* [6] can survive in harsh settings, including disinfectants, which can serve as the initial source for an outbreak.[6] Most infections have been associated with hospital outbreaks.[5] In neonatal intensive care units (NICUs) or pediatric intensive care units (PICUs), outbreaks have been associated with contaminated milk[7], parenteral nutrition or medication,[8] liquid soap,[12] tap water, or hospital equipment, and further dissemination has occurred through the hands of healthcare personnel.[3,6–14] Additional risk factors include the use of intravenous or urinary catheters, ventilator treatment, long duration of hospitalization, previous antibiotic therapy, and underlying conditions such as birth weight less than 1500g, prematurity, diabetes mellitus, and altered host immunity.[15–17]

In a national point-prevalence survey of PICU-acquired infections, *S. marcescens* was the 10th ranked organism, accounting for 2% of all PICU-acquired infections.[18] In a review of 276 NICU outbreaks that occurred in different parts of the world, *Serratia* spp. accounted for 12% of outbreaks, was the third most common pathogen, and had a mortality rate up to 7.7%.[19] In an outbreak setting, genotyping of the isolates by pulse field electrophoresis or polymerase chain reaction (PCR)–based methods should be performed.[5,15] Consecutive outbreaks occurring over 3 to 10 years in the NICU have been associated with different clones that were circulating for long periods.[5,20,21]

The most common sites for colonization are the respiratory and gastrointestinal tract in infants and the respiratory tract in adults.[25] Prolonged colonization can occur, particularly in immunocompromised hosts.[22]

Clinical Manifestations

Nosocomial Infections.

In neonates, the symptoms and signs of sepsis or meningitis due to *S. marcescens* are indistinguishable from those caused by other pathogens, but the mortality rate can be as high as 44%.[16,23,24] Neonatal meningitis can occur in 11% to 25% of infants with *S. marcescens* bloodstream infections (BSIs), and up to 50% of cerebrospinal fluid (CSF) specimens can have a normal cell count and glucose level, whereas the protein concentration usually is elevated.[16,25] In a study involving almost 9000 infants discharged from 333 NICUs, isolation of *S. marcescens* (and *S. pneumoniae*) from CSF showed the highest concordance with blood compared with other pathogens in infants with (22%) or without (10%) ventriculoperitoneal shunt infections.[25]

Meningitis can develop while on therapy for sepsis and can be associated with ventriculitis, hydrocephalus, or brain parenchyma destruction. These processes can lead to loculated areas of infection or cyst formation, similar to infections caused by *Enterobacter sakazakii* and *Citrobacter* spp. Serial neuroimaging studies should be performed during therapy.[26] Most survivors are neurologically impaired.[25]

In children, *S. marcescens* is associated with BSI, pneumonia, urinary tract infection (UTI), meningitis with or without brain abscess, bone and joint infection,[27] ocular infection, intra-abdominal infection (including peritonitis in patients undergoing dialysis),[28] and wound infection (including surgical site infection).[15,16,27,28] Although uncommon, necrotizing fasciitis due to *S. marcescens* in previously healthy children has been reported.[29,30] In older children and adults, isolation of *Serratia* spp. invariably is associated with an indwelling catheter and instrumentation (e.g., tracheostomy, ventilator use, bronchoscopy), causing UTIs and nosocomial pneumonia.[5,31] Endocarditis is mainly diagnosed in intravenous drug users. *S. marcescens* and *Serratia* spp. also are responsible for a large proportion of eye infections, including keratitis, corneal ulcers, conjunctivitis, and endophthalmitis.[32,33] The latter is associated with poor outcomes and can lead to complete visual loss.[34]

Community-Acquired Infections.

Serratia infections acquired in the community can occur in children with chronic granulomatous disease (CGD) and may represent the sentinel infection that leads to the diagnosis of this disorder. The estimated incidence of *Serratia* infections in CGD patients is up to

0.98 cases per 100 patient-years, with a recurrence rate of 18%. Lymphadenitis and skin abscesses are the most common infections (44%), followed by pulmonary infections (36%) and osteomyelitis (8%).[35] Any child with a community-acquired infection due to a *Serratia* spp., particularly infection of bone or lymph nodes, should be evaluated for CGD.

Treatment

Serratia spp. are intrinsically resistant to ampicillin and amoxicillin with or without β-lactamase inhibitors, first-generation cephalosporins, macrolides, nitrofurantoin, and colistin, but they can be resistant to broader-spectrum antimicrobial agents through different mechanisms of resistance.[5] Treatment of *Serratia* spp. infections can be challenging, and every effort should be made to identify the source in an outbreak setting to limit the spread of the organism by stringent cohorting of cases and aggressive education regarding handwashing by healthcare personnel.[15,36] Infected patients should be monitored for clinical responses during treatment, and if suboptimal or cultures remain positive, susceptibility testing should be repeated and therapy adjusted accordingly.

There are several mechanisms of resistance. First, inducible chromosomal AmpC-type β-lactamases (see Chapter 140) can be expressed at a low level and may not be detected in standard laboratory susceptibility tests. However, the genes coding for these enzymes can be induced or derepressed, leading to high-level enzyme production as early as 3 to 4 days into therapy.[37] Treatment failures using monotherapy with a third-generation β-lactam antibiotic can occur. In the laboratory, resistance to cefoxitin is a good indicator for the detection of AmpC production. Second, *Serratia* spp. less frequently also carries extended-spectrum β-lactamases (ESBLs), which are plasmid encoded.[38,39] Resistance to third-generation cephalosporins can be an indicator of ESBLs in a *Serratia* isolate. Third, carbapenemases have been found to a lesser extent in *S. marcescens,* including serine carbapenemases such as plasmid-borne KPC-type and chromosomal SME-type enzymes and plasmid-borne metallocarbapenemases, including IMP-, VIM-, and NDM-type enzymes.[40–43] Fourth, carbapenem resistance in *S.*

marcescens can be mediated by hyperproduction of AmpC-type β-lactamases along with mutations of outer membrane porin proteins.[44]

The Clinical and Laboratory Standards Institute (CLSI) recommendations for the screening and confirmation of AmpC and ESBL enzymes in *Serratia* spp. are not standard. However, in 2014, CLSI recommended the adoption of the revised susceptibility test breakpoints for the Enterobacteriaceae to more accurately categorize the susceptibility of β-lactamase-producing isolates.[37] Using the revised CLSI breakpoints for carbapenems, 1119 *Serratia* spp. were analyzed. The greatest effect was in the drop in susceptibility to imipenem to 92.9%, but there was no significant change in susceptibility to other carbapenems: ertapenem (98%), meropenem (98.8%), and doripenem (98.8%).[37,38,45]

Antibiotic selection depends on the severity of the infection, ability of the drug to penetrate into the infected areas (especially in the setting of retained material), in vitro susceptibility, and the likelihood of emerging drug resistance during the course of treatment. *Serratia* spp. are susceptible to fluoroquinolones, aminoglycosides, thrimethoprim-sulfamethoxazole, piperacillin-tazobactam, ticarcillin-clavulanate, third- and four-generation cephalosporins, and carbapenems.[46] Nevertheless, source control is the key and may include removal of prosthetic material or invasive devices, and adequate drainage and debridement of infected tissue. For uncomplicated infections (i.e., UTI) in the setting of susceptible isolates, antibiotic monotherapy is warranted. For the treatment of severe infections, empiric treatment should include a carbapenem, an extended-spectrum cephalosporin, or absent central nervous system involvement, an extended-spectrum β-lactam/β-lactamase inhibitor combination plus an aminoglycoside.

A study of hospitalized patients with invasive infections caused by AmpC β-lactamase–producing Enterobacteriaceae showed no differences in the 30-day mortality rate or length of hospital stay for patients who received cefepime versus meropenem.[47] In this study, *Serratia* spp. represented 22% of all isolates, and 15% of them were phenotypically confirmed as Amp-C β-lactamase producers. Cefepime may be a reasonable option for the treatment of invasive *Serratia* infections as long as adequate source control is achieved.[47] For infections with *Serratia* spp. that produce ESBL, a carbapenem remains the drug of choice.

For neonatal meningitis caused by *Serratia* spp., CSF cultures should be performed repeatedly until sterility is confirmed.[24] Therapy should be continued for a minimum of 21 days or for 10 to 14 days after CSF sterility has been documented, whichever is longer. Imaging studies should guide medical and surgical management. Between 4 and 8 weeks of antibiotic therapy may be required for infants with ventriculitis, abscesses, encephalitis, or infarction.

Acknowledgments

We acknowledge the substantial contributions of D.A. Powell and M.J. Marcon to this chapter in previous editions.

Key Points

Diagnosis and Management of *Serratia* Infections

Microbiology

- Facultative anaerobic, catalase-positive, gram-negative bacillus
- Of all *Serratia* spp, *Serratia marcescens* is most commonly isolated in human infections.

Epidemiology

- Environmental organism, rarely causes infections in healthy hosts.
- Nosocomial pathogen is mainly associated with outbreaks in neonatal or pediatric intensive care units.
- Children with community-acquired infection should be evaluated for chronic granulomatous disease.

Clinical Manifestations

- Can involve various organ systems
- Urinary tract infection common in older children

Diagnosis

- Organism can be recovered from all sample types using standard culture.
- Genotyping of the isolates should be performed in the setting of an outbreak.

Treatment

- Can harbor various mechanisms of resistance, primarily intrinsic chromosomal AmpC-type β-lactamase, followed by extended-spectrum β-lactamase (ESBL) or carbapenemase.
- For severe infections, empiric treatment should include a carbapenem, an extended-spectrum cephalosporin, or an extended-spectrum β-lactam/β-lactamase inhibitor combination plus an aminoglycoside.

Salmonella Species

Megan E. Reller

Nontyphoidal *Salmonella* species are found widely in animals and cause a broad spectrum of clinical infections that include asymptomatic carriage, gastroenteritis, bacteremia, and metastatic focal infections. In contrast, *Salmonella* serotypes Typhi and Paratyphi A are human-specific pathogens that cause typhoid or enteric fever, a protracted febrile illness with myriad manifestations.

Description of the Pathogen

Salmonella species are gram-negative bacilli that belong to the family Enterobacteriaceae. They ferment glucose, reduce nitrate to nitrite, and are oxidase negative. *Salmonella* are indole negative and, with rare exceptions, are motile and lactose negative.

All *Salmonella* organisms are closely related by DNA-DNA hybridization studies. Clinically important *Salmonella* consist principally of a single species, *Salmonella enterica.*[1] Although more than 2500 serotypes of *Salmonella* have been described, fewer than 100 serotypes cause most human infections. Reactions of *Salmonella* with antisera to specific O (somatic) antigens determine the serogroups A, B, C_1, C_2, D, and E; O, H (flagellar), and Vi (capsular) antigenic characterization results in a unique serotype that traditionally has served as a surrogate species designation. The Centers for Disease Control and Prevention (CDC) published guidelines to clarify *Salmonella* nomenclature (Table 146.1).[1]

TABLE 146.1

Salmonella Nomenclature

Complete Name	CDC Designation	Common Clinical Usage (Recommended)
***Salmonella enterica* subsp. *enterica* ser. Typhi**	*Salmonella* ser. Typhi	*Salmonella typhi* (Typhi)
***Salmonella enterica* subsp. *enterica* ser. Paratyphi A**	*Salmonella* ser. Paratyphi A	*Salmonella paratyphi* A (Paratyphi A)
***Salmonella enterica* subsp. *enterica* ser. Typhimurium**	*Salmonella* ser. Typhimurium	*Salmonella typhimurium* (Typhimurium)
***Salmonella enterica* subsp. *enterica* ser. Enteritidis**	*Salmonella* ser. Enteritidis	*Salmonella enteritidis* (Enteritidis)
***Salmonella enterica* subsp. *enterica* ser. Dublin**	*Salmonella* ser. Dublin	*Salmonella dublin* (Dublin)

CDC, Centers for Disease Control and Prevention; ser., serotype; subsp., subspecies.

Modified from Brenner FW, Villar RG, Angulo FJ, et al. *Salmonella* nomenclature. J Clin Microbiol 2000;38:2465.

The pathogenesis of *Salmonella* infections is complex, but it is being unraveled because genome sequencing has provided a complete blueprint of the genetic repertoire for several serotypes of *S. enterica,* including *S.* Typhimurium, *S.* Typhi, and *S.* Paratyphi.[2] Examination of the *S.* Typhi genome has identified up to 10 pathogenicity islands, and comparisons with the *S.* Typhimurium genome have disclosed other smaller *S.* Typhi–specific gene clusters or individual genes. Further studies of virulence genes should enable an understanding, for example, of why *S.* Typhi infects only humans and why the rare animal serotype *S.* Dublin is almost 80-fold more likely to invade the bloodstream than is *S.* Typhimurium.[3]

Most nontyphoidal *Salmonella* do not extend beyond the lamina propria and local lymphatics of the gut, whereas *S.* Choleraesuis and *S.* Dublin rapidly cause bacteremia with little or no intestinal involvement. The quintessential invasive serotype is *S.* Typhi, which can cause intestinal perforation.[2,4–6] On reaching the small intestine, *S.* Typhi adheres to the specialized epithelial M cells overlying Peyer patches. Penetration of the mucosa includes cytokine secretion (e.g., interleukin-8, interleukin-6), uptake by macrophages, and translocation to lymphoid follicles in the gut and the draining lymph nodes. An asymptomatic bacteremia disseminates *S.* Typhi throughout the body, where the bacteria survive and multiply within mononuclear cells of the liver, spleen, and bone marrow. After an incubation period of 7 to 14 days, a sustained secondary bacteremia heralds the onset of symptoms.

Many factors predispose to *Salmonella* infection (Table 146.2). The incubation period, symptoms, and clinical severity vary with the number of organisms ingested. Relative hypochlorhydria and rapid gastric emptying help explain the relative vulnerability of neonates and young infants to symptomatic salmonellosis.[6,7]

TABLE 146.2

Factors Predisposing to *Salmonella* Infection or Dissemination

Site of Defect	Mechanism and Clinical Setting
Gastric acid barrier	Achlorhydria
	Anatomic: gastrectomy, gastroenterostomy
	Functional: ingestion of buffers, vagotomy
	Rapid emptying (neonates, postgastrectomy)
Intestinal mucosal barrier	Inflammatory bowel disease
	Tissue ischemia or infarction (sickle cell anemia, trauma)
Gut flora	Prior antimicrobial therapy (results in increased infection and prolonged carriage)
Opsonins	Sickle cell anemia (defect in alternative complement pathway)
Neutrophils	Chronic granulomatous disease
Cell-mediated immunity	After organ transplantation or with defects associated with acquired immunodeficiency syndrome, infancy, malnutrition, or corticosteroid therapy
	Defects in type 1 helper T-lymphocyte (Th1) functions (interleukin-12 and interferon γ axis), including mutations in the genes for interleukin-12Rβ1 and interleukin-12
Sequestered organisms	Schistosomiasis
	Reticuloendothelial cells (typhoid fever)
	Solid tumors
	Gallbladder disease
Reticuloendothelial system	Overload with hemoglobin or iron (hemolytic anemia as in sickle cell disease, thalassemia, bartonellosis, and malaria) or impaired function due to malignancy such as leukemia or lymphoma

Impaired reticuloendothelial or cellular immune response raises the risk for severe, complicated infection.[7,8] Children with sickle cell disease are prone to septicemia and osteomyelitis when infected with nontyphoidal *Salmonella.* Decreases in phagocytic and opsonizing capacity of patients with sickle cell disease, along with infarcts in the gastrointestinal tract, bones, and reticuloendothelial system, contribute to the high infection rate.

Epidemiology

Nontyphoidal *Salmonella*

Since 2005, between 45,000 and 51,000 cases of culture-proven nontyphoidal salmonellosis have been reported each year in the United States; however, an estimated 1.4 million diarrheal illnesses and 600 deaths annually are attributed to *Salmonella*.[8–12] About one third of cases occur in children younger than 4 years of age, and children in the first few months of life have the highest incidence.

Nontyphoidal *Salmonella* infections have worldwide distribution, with a prevalence that varies according to public health standards, water treatment, sewage disposal, animal exposures, and food-handling practices. More *Salmonella* infections occur during warm summer months in temperate climates. Nontyphoidal *Salmonella* are the most common cause of culture-confirmed foodborne infection in the United States.[12] *S*. Enteritidis and *S*. Typhimurium have been the most commonly identified serotypes in the United States since 1996 (www.cdc.gov/narms).

The Foodborne Surveillance Network (i.e., FoodNet), a collaborative program among state health departments, the US Department of Agriculture, the US Food and Drug Administration (FDA), and CDC, was established in 1996 and has enhanced outbreak recognition by adding pulsed-field gel electrophoresis analyses to traditional serotyping.[9–12]

The major reservoir of nontyphoidal *Salmonella* is the gastrointestinal tract of infected, often asymptomatic birds, mammals, and reptiles. Chickens, turkeys, ducks, sheep, cows, pigs, and various pets, especially turtles, snakes, lizards, iguanas, chicks, ducklings, and hedgehogs, commonly are infected.[13–17] Some serotypes can be isolated from a variety of cold- and warm-blooded animals; others are relatively restricted (Table 146.3). Isolation of an uncommon serotype can suggest a likely source of infection. Illness can result from exposure to pets and animals in public settings and from environmental contamination even without direct contact with an infected animal.[18,19] Handling pet food treats containing dried beef and chicken has caused infections.[20,21] Handwashing after exposure to pets and animals, their food, and environments is essential.

TABLE 146.3

Examples of *Salmonella* Serotypes Associated With Cold-Blooded and Warm-Blooded Animals

Animal Reservoir	Serotypes Isolated
Snake	Arizonae, Montevideo, Eingedi
Iguana	Marina, Montevideo, Poona
Lizard	Poona
Komodo dragon	Enteritidis
Terrapin	Tel-el-kebir
Turtle	Pomona, Chester, Typhimurium, Muenchen, Java
Gecko	Weltevreden, Typhimurium, Enteritidis, Saintpaul, Agama
Crocodile	Typhimurium, Tsevie, Duval, Schwerin, Tinda, Tallahassee
Chicken	Typhimurium, Enteritidis, Heidelberg, Hadar, Montevideo, Thompson, Berta, Livingstone, Virchow
Turkey	Kentucky, Anatum, Heidelberg, Reading, Senftenberg, Saintpaul
Pig	Infantis, Choleraesuis, Typhimurium
Cattle	Dublin, Typhimurium
Hedgehog	Tilene

Salmonella are the leading cause of foodborne outbreaks and outbreak-related hospitalization, and infections are especially common and severe in young children.[12] *Salmonella* serotypes have been isolated from 20% to 75% of fresh or thawed retail poultry samples, and they are found in pork, beef, and frozen egg products. Foods containing raw or undercooked eggs (e.g., Caesar salad, egg-dipped bread, homemade eggnog) can be contaminated. Eggs become contaminated by *Salmonella* that penetrate the egg from the shell surface or from direct transovarian inoculation to the egg yolk. Dairy products also have been incriminated as sources of human infection. *Salmonella* can be killed by heating to 54.4°C for 1 hour or 60°C for 15 minutes, but the organisms remain viable at ambient or reduced temperatures for days to weeks.

The number of bacteria that must be ingested to cause symptomatic disease in healthy adults is 10^6 to 10^8 nontyphoidal *Salmonella* organisms.[22] A smaller inoculum can produce disease in infants and toddlers and when ingested with foods rich in fat (e.g., cheese, chocolate, peanut butter). Nursery outbreaks are a result of several factors, including neonatal susceptibility to low numbers of *Salmonella.* Transplacental infection and perinatal transmission during vaginal delivery have been reported.[23] Healthcare-associated infections have been related to contaminated medical equipment (e.g., endoscopes) and diagnostic or pharmacologic preparations, particularly those of animal origin (e.g., pituitary extracts, bile salts, pancreatic extracts, pepsin, vitamins).

After infection, nontyphoidal salmonellae are excreted in feces for a median of 5 weeks. In infected children younger than 5 years of age, excretion is prolonged. Approximately 40% of these children excrete organisms for 20 weeks after illness. In older children and adults, *Salmonella* excretion lasting more than 8 weeks after infection is uncommon, but antimicrobial therapy may prolong excretion.

Emerging antimicrobial resistance of animal-associated serotypes of *Salmonella* has become an international public health problem, especially in industrialized countries.[24] A zoonotic strain of *S.* Enteritidis known as definitive phage type 104 (DT104) with chromosomal resistance to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline was recognized in the 1990s in the United States and several countries in Europe.[8] Subsequently, clonal spread of fluoroquinolone-resistant DT104 strains from food animals to humans was documented in Denmark.[24] In the United States in 2000 and Canada in 2002, cattle-associated multidrug-resistant strains of *S.* Newport with plasmid-encoded AmpC β-lactamase were isolated from ill children.[25] These ceftriaxone-resistant Newport-MDR AmpC strains were estimated by the CDC to cause more than 20,000 *Salmonella* infections in 2001 alone.[25]

Although most extended-spectrum cephalosporin resistance is attributed to plasmid-encoded AmpC β-lactamases, extended-spectrum β-lactamases have been reported.[26] Fluoroquinolone-resistant, invasive *S.* Choleraesuis strains in Taiwan have spread to humans from pigs, and life-threatening infantile diarrhea has resulted from highly resistant *S.* Typhimurium with mutations in the *gyrA* and *parC* genes.[27,28] These events led to the restriction or prohibition in food animals of fluoroquinolones and other antimicrobial agents used for treating human disease.[24–28]

In the United States, resistance among nontyphoidal *Salmonella* isolates submitted to the National Antimicrobial Resistance Monitoring System (NARMS) has decreased over the past decade. Approximately 3% of nontyphoidal isolates in the United States are resistant to ceftriaxone, and 5% are resistant to more than four antimicrobial agents (http://www.cdc.gov/narms/pdf/2012-annual-report-narms-508c.pdf). Patients with resistant organisms were more likely to have bacteremia and to be hospitalized compared with those with fully susceptible isolates.[29]

The scourge of multidrug-resistant nontyphoidal *Salmonella* has not spared Africa, where unregulated over-the-counter sale of antimicrobial agents rather than use in animals has fueled resistance.[30] Over the past decade, increasing resistance encoded on large, self-transferable plasmids has been documented in 30% to 80% of *S.* Typhimurium and *S.* Enteritidis cases, which account for almost 80% of the nontyphoidal *Salmonella* isolated from blood, feces and cerebrospinal fluid in Kenyan studies.[30]

Salmonella Typhi

The worldwide disease burden of typhoid and paratyphoid fever is estimated to approach 27 million illnesses, with up to 600,000 deaths yearly.[6,31] The impoverished and children suffer disproportionately, especially in south central and southeast Asia and southern Africa.[32] About 300 cases of typhoid fever are reported annually in the United States; almost 80% occur in travelers to or visitors from highly endemic areas, especially the Indian subcontinent, and children account for about 40% of cases.[33]

Because *S.* Typhi and Paratyphi A have no animal reservoir, fecal contamination of food or drink by ill, convalescing, or asymptomatically infected people accounts for most cases of enteric fever. Infection by person-to-person contact is thought to be rare, but sexual transmission has been documented.[34] The inoculum required for *S.* Typhi varies between 1000 and 1 million organisms, which is about 1000-fold lower than that customarily associated with other *Salmonella* infections.[6,22] Systemic and local humoral and cellular immune responses result from typhoid infection, but immunity is not robust and confers incomplete protection from relapse and reinfection.[6]

Antimicrobial resistance of *S.* Typhi to chloramphenicol became widely recognized in the 1970s, and plasmid-mediated multidrug resistance emerged in the 1990s. These multidrug-resistant strains commonly were resistant to all drugs used for initial treatment of enteric fever (i.e., ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole).[6] Resistance to fluoroquinolones has become widespread, and ceftriaxone resistance is emerging. Reports buttressed by elegant molecular studies have documented multidrug-resistant clones of *S*. Typhi in Africa and Asia, which now account for 85% to 100% of outbreak strains in Kenya.[35,36] These patterns of resistance appear to be shifting with changing pressures in antimicrobial use. Fluoroquinolone-resistant *S*. Typhi and *S*. Paratyphi A is an emerging problem in India, Korea, and Nepal as fluoroquinolone use increases.[37–40] In some studies, 10% of *S*. Typhi and 14% of *S*. Paratyphi A isolates are fluoroquinolone resistant. Despite this steady rise in fluoroquinolone resistance, strains susceptible to ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole are re-emerging.[38,40] Because high cost has restricted use, ceftriaxone resistance remains low in these areas.[38]

Clinical Manifestations

Several clinical syndromes can develop in children infected with *Salmonella,* depending on host factors and the specific serotype involved.

Gastroenteritis

Gastroenteritis is the most common clinical presentation of nontyphoidal *Salmonella* infection. After an incubation period of 6 to 72 hours (mean, 24 hours), abrupt onset of nausea, vomiting, and cramping abdominal pain is followed by watery or dysenteric (i.e., containing blood and mucus) diarrhea. Fever (38.5°C–39°C) occurs in approximately 70% of cases, and the abdomen can be tender. Feces may contain neutrophils and occult blood. Patients commonly have mild peripheral blood leukocytosis with a left shift.

Symptoms subside in less than 1 week in most healthy children. In neonates, young infants, and children with immunodeficiency, symptoms can persist for weeks. In patients with AIDS, the infection can disseminate, with multisystem involvement, shock, and death. In patients with inflammatory bowel disease, especially active ulcerative colitis, *Salmonella* gastroenteritis can be associated with invasion of the bowel wall and rapid development of toxic megacolon, systemic toxicity, and death. Reactive arthritis without clinical joint infection follows *Salmonella* gastroenteritis in 2% of cases, usually in adolescents or adults with the human leukocyte antigen B27 (HLA-B27) antigen. The duration of fecal shedding (median, 7 weeks) after symptoms subside can be prolonged in children younger than 5 years of age.[6]

Bloodstream Infection

Nontyphoidal *Salmonella* gastroenteritis is complicated by transient bacteremia that is usually associated with fever, chills, and toxicity in 1% to 5% of patients overall and more frequently in infants and malnourished children.[41,42] *S.* Typhimurium and *S.* Enteritidis are the most common serotypes associated with bloodstream infections (BSIs) in the United States.[7,30,42,43] Certain serotypes (e.g., Choleraesuis, Dublin) cause bacteremia more often than they cause gastroenteritis.[5,27] Children, especially neonates, may be afebrile and nontoxic.

The occurrence, morbidity, and mortality of nontyphoidal *Salmonella* BSIs are related to age and underlying conditions. Infants with BSI (~20% of cases) uncommonly are immunocompromised apart from age, whereas older children usually have a predisposing condition.[44] Death is more common if the patient has an underlying condition. Metastatic foci of infection and death are more common in the first year of life.[7,45]

Nontyphoidal *Salmonella* BSI commonly persists when treated with oral antibiotics or single-dose parenteral antibiotics. Laboratory and clinical findings do not predict adequately which children will experience persistent bacteremia. Approximately 35% of immunocompromised children develop serious focal infections (e.g., meningitis, osteomyelitis, pyogenic arthritis, pneumonia) after *Salmonella* bacteremia, whereas previously healthy children are at relatively low risk (3%).[46–48]

Recurrent *Salmonella* septicemia without an obvious focus sometimes complicates infection in people with AIDS and occurs despite antibiotic therapy.[7,8] Prolonged or recurrent bacteremia also occurs in patients with schistosomiasis, who exhibit persistence of infection unless the schistosomiasis also is treated. *Salmonella* organisms can multiply within the schistosomes, where they are protected from antimicrobial agents. Hemolytic anemia, such as that occurring with sickle cell disease, malaria, and *Bartonella* *bacilliformis* infection, is associated with a higher risk of bacteremia, presumably because of blockade of the reticuloendothelial system. Invasive nontyphoidal salmonellosis during pregnancy in otherwise healthy women is rare, and prognosis for the mother is favorable, but transplacental infection usually is lethal for the fetus.[23]

Extraintestinal Focal Infections

Salmonella can cause metastatic infection in almost any organ. Sites with preexisting anatomic abnormalities typically are involved (e.g., polycystic kidney or liver, hyperplastic lymph nodes, tumor). Bone infections due to *Salmonella* occur in infarcted bone of children with sickle cell disease. Osteomyelitis and suppurative arthritis can develop at sites of previous trauma, in skeletal prostheses, and occasionally without any predisposing factor.[8] Infants younger than 2 months of age with *Salmonella* gastroenteritis have an increased risk of bacteremia, meningitis, and other foci of infection. Meningitis is primarily a disease of infants; neonates may have little or no fever initially but have rapid deterioration, high mortality rates (~50%), and neurologic sequelae among survivors.[7,30,49–52] Rarely, other focal infections such as urinary tract infection, pericarditis, peritonitis, pneumonia, and empyema complicate *Salmonella* bacteremia.[53]

Enteric Fever

Although enteric fever (i.e., typhoid fever) classically is associated with *S.* Typhi and *S.* Paratyphi, other *Salmonella* strains occasionally cause disease mimicking this syndrome.[6,31,54–57] The clinical features of enteric fever with *S.* Typhi or *S.* Paratyphi are indistinguishable. During the first week of illness, there is a stepwise, insidious increase in fever, which eventually becomes unremitting and is associated with systemic symptoms such as headache, lethargy, malaise, myalgia, and abdominal pain. In the second week, hepatosplenomegaly occurs, and rose spots may be seen; headache is replaced by stupor. Relative bradycardia is not a feature of typhoid fever in children.[58] During the third to fourth week of fever, intestinal hemorrhage and perforation are common; fever begins to show morning remissions, and there is a gradual decline in fever spikes. Myocarditis, shock, meningitis, and pneumonia can complicate the course.[59]

During the first several weeks of illness, children often have diarrhea with blood and fecal leukocytes, although in a few patients, diarrhea does not begin until the third week. Occasionally, resolution does not occur until 6 weeks after onset. Even in the preantibiotic era, recurrences were sometimes seen after apparent resolution. Death related to central nervous system involvement, intestinal hemorrhage, or perforation usually does not occur until after the first week of illness. In infants and young children, *S.* Typhi can cause less impressive fever and toxicity, and the resultant nonspecific syndrome can be misinterpreted as a viral infection.

Asymptomatic Infection

After clinical recovery from nontyphoidal *Salmonella* gastroenteritis, asymptomatic fecal excretion of *Salmonella* continues for weeks and can be a source for contamination of food or drink and transmission to others.[8] Excretion of *Salmonella* for several months is typical in infants infected very early in life. Asymptomatic fecal excretion for weeks is also seen after typhoid fever in all ages. The role of convalescing excreters of *S.* Typhi among children in endemic areas is more important than chronic carriage in perpetuating transmission. Convalescent (≤1 year) and chronic (>1 year) carriage in adults is a consequence of biliary tract disease, especially gallstones, which usually are asymptomatic.[33]

Laboratory Findings and Diagnostic Tests

Gastroenteritis is best diagnosed by cultures of stool specimens rather than rectal swab specimens. Selective media that inhibit the growth of normal flora, such as MacConkey, Hektoen enteric, or xylose-lysine-deoxycholate (XLD) agar, should be used. Enrichment broth (e.g., selenite F) can be used to enhance isolation when low numbers of *Salmonella* are present in stools. Rare lactose-fermenting *Salmonella* may pose a diagnostic problem, but other biochemical features enable accurate identification.[60]

Blood cultures are the best method for diagnosing typhoid fever and BSIs that can complicate other *Salmonella* infections.[6,31,55–59] The sensitivity of blood cultures (60% to 80%) depends principally on the volume of blood sampled in children and adults.[6] Quantitative studies have shown a median of 0.3 organisms/mL (interquartile range, 0.1 to 10 organisms/mL) in blood compared with 9 organisms/mL (interquartile range, 1.0 to 85 organisms/mL) in bone marrow.[61] A minimum of 1 to 15 mL of blood, depending on the age and weight of the child, should be cultured.[6]

Culture of bone marrow is more sensitive (80% to 95%), but it is done less often because most children in endemic areas are treated outside the hospital. Bone marrow cultures may be useful when the diagnosis is elusive for persistently febrile patients. Metastatic focal infections that can complicate infection due to many *Salmonella* serotypes are best diagnosed by cultures of aspirates of pus, biopsy specimens, or cerebrospinal fluid.[8,31]

Given the worldwide prevalence of multidrug-resistant *Salmonella,* accurate antimicrobial susceptibility testing in accord with Clinical Laboratory Standards Institute (CSLI) methods and interpretive criteria is imperative, and results should guide or refine therapy.[62] For fecal isolates of *Salmonella,* only ampicillin, a fluoroquinolone, and trimethoprim-sulfamethoxazole should be tested and reported routinely. Chloramphenicol and an extended-spectrum cephalosporin should be tested for extraintestinal isolates. Resistance to nalidixic acid is a practical but imperfect surrogate test for gyrase (i.e., *gyrA* and *gyrB*) and topoisomerase IV (i.e., *parA* and *parC*) mutations that render isolates less responsive or refractory to fluoroquinolone therapy. Additional resistance mechanisms for fluoroquinolones include plasmid-mediated resistance encoded on *qnr* or *aac*(6′)-*Ib-cr*.[40] Although resistance to extended-spectrum β-lactams and carbapenems have been found in nontyphoidal *Salmonella*, few cases in *S*. Typhi have been reported.[31,40] Investigational interpretive criteria for susceptibility testing of *S*. Typhi to azithromycin were published by CLSI in 2015.

Clinically, *Salmonella* gastroenteritis cannot be distinguished easily from other bacterial causes of bloody diarrhea, although age, exposures, fever, associated enteritis symptoms, and various epidemiologic features sometimes suggest an etiologic agent.

Inflammatory diarrhea with fever also is consistent with *Shigella,* enteroinvasive *Escherichia coli,* enterohemorrhagic *E. coli, Campylobacter jejuni, Yersinia enterocolitica,* and *Clostridium difficile* infections. *Trichuris trichiura, Balantidium coli,* and *Entamoeba histolytica* are important possible parasitic causes of bloody mucoid diarrhea. When abdominal pain and tenderness are severe, alternative diagnoses such as appendicitis, perforated viscus, and ulcerative colitis merit consideration. Typhoid fever can mimic other infections of the reticuloendothelial system, including Epstein-Barr virus infection, disseminated tuberculosis, histoplasmosis, ehrlichiosis, anaplasmosis, brucellosis, tularemia, plague, and murine typhus.

Treatment

For people with gastroenteritis, initial therapy focuses on rehydration, correction of electrolyte disturbances, and general supportive care. Antimicrobial agents usually are not indicated for uncomplicated gastroenteritis because they do not speed resolution of symptoms. Rather than eliminating fecal excretion, antimicrobial agents can prolong colonization. Antimicrobial therapy may be appropriate for patients with gastroenteritis who are at high risk for complications, although the efficacy of this measure is unproved.

Suspected or proven BSIs and extraintestinal focal *Salmonella* infections should be treated with a third-generation cephalosporin unless susceptibility data demonstrate that the organism is susceptible to ampicillin, trimethoprim-sulfamethoxazole, or chloramphenicol; usual doses are listed in Table 146.4. Considering the intracellular site of *Salmonella* in the reticuloendothelial system, trimethoprim-sulfamethoxazole or fluoroquinolones may have a theoretical advantage over ampicillin for treatment of enteric fever. About 40% of nontyphoidal *Salmonella* isolates in the United States are resistant to one or more antimicrobial agents; worldwide multidrug resistance of all *Salmonella* serotypes is increasing.[3,6,20,24–30,35–40] Fluoroquinolones are best avoided in children younger than 18 years of age unless alternative agents are not available.[6]

TABLE 146.4

Antimicrobial Agents for Extraintestinal *Salmonella* Infections[a]

Drug	Dosage
Ampicillin	200 mg/kg/day in 4 divided doses daily
Azithromycin	10 mg/kg once daily for 7 days
Trimethoprim-sulfamethoxazole	10 mg/kg/day of trimethoprim in 2 divided doses daily
Ceftriaxone	100 mg/kg/day in 1 or 2 divided doses daily
Chloramphenicol	50–75 mg/kg/day in 4 divided doses daily

[a] Serotype, site infected, and susceptibility determine optimal agent and duration of therapy.

Duration of therapy depends on the serotype and site of infection. Therapy usually is continued for 10 to 14 days for children with BSI, for 4 to 6 weeks for acute osteomyelitis, and for 4 weeks for meningitis.[8,59] Meningitis can recur even after 4 weeks of therapy, although most patients who have relapses have received less than 3 weeks of antimicrobial therapy. Surgical drainage of focal purulent collections is indicated.[59] In the developing world, *Salmonella* infection associated with schistosomiasis requires treatment of both infections to achieve resolution.

S. Typhi infection usually is treated with a minimum of 10 to 14 days of therapy. Ceftriaxone is the best initial parenteral choice because of widespread resistance to other agents. For susceptible strains, ampicillin, trimethoprim-sulfamethoxazole, and chloramphenicol have been used successfully, and fluoroquinolones have been used extensively, even in children in endemic areas.[6,31] Defervescence in typhoid fever usually requires at least 36 hours of therapy, and fever can persist for 5 to 7 days, even with ultimately effective therapy.

Azithromycin has been effective in children with strains resistant to first-line agents.[63,64] Corticosteroids are used as adjunctive therapy for delirium, obtundation, stupor, coma, or shock in children with typhoid fever. A dose of 3 mg/kg of dexamethasone initially, followed by 1 mg/kg every 6 hours for 48 hours, was associated with reduction of the mortality rate from between 35% and 55% to 10%.[65] For patients in whom intestinal perforation develops, surgery coupled with broad-spectrum antimicrobial therapy directed at anaerobic and gram-negative enteric bacteria is indicated. The mortality rate after perforation can be as high as 10% to 30%.[6]

Special Considerations

Immunocompetent children with *Salmonella* gastroenteritis usually have an uneventful recovery without antimicrobial therapy. Young infants and immunocompromised patients, particularly patients with focal infection, can have prolonged, complicated courses. *Salmonella* meningitis has a poor prognosis and high relapse rate, particularly if treated with too short a course of therapy. Antimicrobial-resistant nontyphoidal *Salmonella* is associated with excess BSIs, hospitalizations, and deaths.[5,66]

Even with appropriate therapy, patients can have recurrence of typhoid fever after completion of therapy (i.e., 5% to 20% relapse rate). Relapses of *Salmonella* infections presumably reflect the difficulty in killing intracellular organisms. Because relapse sometimes results from resistant bacteria, an agent different from the initial drug should be used empirically while awaiting culture and susceptibility test results. Antibiotic-resistant strains of *S.* Typhi are independently associated with increased virulence and adverse outcomes.[67,68]

Prevention

Chlorination of water, proper sewage disposal, and appropriate food-handling practices are necessary to prevent salmonellosis. Hand hygiene is critical to prevent transmission by food. People who excrete *S.* Typhi should be excluded from occupations in food preparation and childcare until results of repeated stool cultures are negative; infected children younger than 5 years of age also are excluded until repeated stool cultures are negative. For nontyphi salmonellosis, recovery from symptomatic disease but not stool culture negativity is required for return to group childcare.[69] For hospitalized infants and children, enteric precautions are recommended because low inocula levels can cause infection in children. Prolonged breastfeeding reduces the infection rate.[70]

No vaccine against nontyphoidal *Salmonella* or *S.* Paratyphi infections is available, although two vaccines are available for *S.* Typhi (Table 146.5).[71–74] The vaccines have similar efficacy, typically in the range of 50% to 75% for reducing the number of laboratory-confirmed cases in 2 to 3 years. Seven-year follow-up data for enteric-coated capsules containing Ty21a live vaccine suggest greater than 60% long-term protection. The live, attenuated vaccine should not be used in immunocompromised hosts or in people receiving antimicrobial agents at the time of immunization. Pediatric use of typhoid vaccines has been limited to children who will travel in areas where prolonged exposure to *S.* Typhi is likely, live where multidrug-resistant strains are prevalent, or are members of households with documented carriers.

TABLE 146.5

Vaccines for Prevention of *Salmonella* Typhi

Vaccine	Age Indicated	Dose and Route	Adverse Reactions
Oral live, attenuated Ty21a vaccine (Vivotif)	≥6 years		0–5% fever or headache
Primary series		1 enteric-coated capsule every 2 days for 4 doses	
Booster (every 5 years)		1 enteric-coated capsule every 2 days for 4 doses	
Vi capsular polysaccharide vaccine (Typhim Vi)	>2 years		0–1% fever, 2–3% headache, 7% redness or induration at injection site
Primary series		Single dose of 0.5 mL (25 μg) IM	
Booster (every 2 years)		Single dose of 0.5 mL (25 μg) IM	

IM, intramuscular.

Mass vaccination of children to prevent typhoid fever in endemic areas is desirable. A substantial proportion of typhoid occurs in children younger than 5 years of age, for whom the oral vaccine is not approved.[54] The World Health Organization (WHO) has recommended widespread use of the Vi vaccine in developing countries in which typhoid fever is endemic, and a recent cluster-randomized trial suggests efficacy in preschool children.[54,74] The *S.* Typhi Vi conjugate vaccine (Vi-rEPA) appears to be effective.[75] Neither of the two FDA-licensed vaccines is effective against *S.* Paratyphi A, which is an emerging, often antibiotic-resistant cause of enteric fever.[37,38]

Key Points

Diagnosis, Management, and Prevention of *Salmonella* Infection

Microbiology

- Gram-negative bacillus, oxidase negative and usually not lactose fermenting
- Characterization based on O (somatic), H (flagellar), and Vi (capsular) antigens
- Chromosomal and plasmid-mediated antimicrobial resistance to ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole; emerging resistance to fluoroquinolones and extended-spectrum cephalosporins

Epidemiology

- Flora of birds, mammals, and reptiles, except *S.* Typhi and *S.* Paratyphi, which are uniquely human pathogens
- Highest prevalence in children <5 years of age, in whom excretion is prolonged
- Person-to-person transmission is rare, especially for *S.* Typhi and *S.* Paratyphi.
- Host factors and serotype contribute to clinical manifestations.
- Classic enteric fever is common with *S.* Typhi and *S.* Paratyphi; gastroenteritis is more common with *S.* Enteritidis and *S.* Typhimurium.
- Immunocompromised children (including those with sickle cell disease) have increased risk of serious focal infections.

Diagnosis

- Recovery from blood (typhoidal disease; infants and malnourished) or stool (nontyphoidal > typhoidal)
- Culture of stool requires selective and inhibitory media to suppress normal flora; enrichment broth enhances isolation.

- Antimicrobial susceptibility testing is imperative, with extended testing for extraintestinal isolates.

Treatment

- Third-generation cephalosporin is empiric choice for bloodstream infection and extraintestinal focal infections.
- Azithromycin has been effective for typhoidal strains resistant to first-line agents.

Duration of Therapy

- Length of therapy depends on serotype, site of infection, and agent used.
- Usual treatment is 10 to 14 days for bloodstream infection, 4 to 6 weeks for acute osteomyelitis, and 4 weeks for meningitis.

Prevention

- Hand hygiene and enteric precautions
- Vaccines for *S.* Typhi

Shigella Species

Shai Ashkenazi

Shigella species cause acute gastrointestinal tract infections, sometimes with extraintestinal manifestations. Shigellosis has substantial public health importance, especially in developing countries, with an estimated 164.7 million annual cases and 1.1 million deaths worldwide.[1] The term *dysentery* denotes colitis manifested as frequent, painful passage of stools containing blood or mucus. Bacillary dysentery is caused by bacteria, including shigellae and enteroinvasive *Escherichia coli* that possess *Shigella* virulence genes.[2,3]

Description of the Pathogen

Shigella organisms are human-adapted *E. coli* that have acquired the ability to invade human intestinal mucosa and cause disease.[3] They are nonmotile, nonencapsulated, gram-negative bacilli in the family Enterobacteriaceae. They do not ferment lactose and lack urease activity. About 50 serotypes, belonging to four serogroups (or species), have been identified: group A *(S. dysenteriae),* group B *(S. flexneri),* group C *(S. boydii),* and group D *(S. sonnei).*

Pathogenesis and Immunity

Shigellosis is one of the most communicable forms of bacterial diarrhea, with as few as 10 organisms causing diarrhea in adult volunteers. The low dose required to cause disease explains the efficiency of person-to-person spread.

The central event in pathogenesis is invasion of colonic mucosa.[4,5] Ingested *Shigella* bacteria cross the colonic epithelium by transcytosis through M cells, the specialized cells that cover the lymphoid follicles of the intestinal mucosa. At the dome area of the lymphoid follicle, the bacteria are phagocytosed by macrophages, which the bacteria kill by inducing apoptosis, dampening the innate immune recognition and evading inflammasome activation.[5,6] With this strategy, shigellae reach the subepithelial tissue and invade colonic epithelial cells through their basolateral surface. During the initial step of cellular entry, shigellae induce actin polymerization in epithelial cells, with formation of filopodes.

After entry, the bacteria free themselves from membrane-bound vacuoles, proliferate in cytoplasm, and spread by actin-based motility. This enables infection of neighboring cells by formation of finger-like protrusions. Intracellular shigellae also reprogram host cells to express proinflammatory cytokines, such as interleukin-1 (IL-1), IL-6, and IL-8, which augment local inflammation and attract neutrophils. Leukocytes transmigrate the epithelium into the lumen of the colon. *Shigella* kills neutrophils by inducing necrosis, and release of granular proteins contributes to further epithelial disruption.[5]

Plasmid and chromosomal virulence genes have been defined in *Shigella* and invasive *E. coli.* Specific chromosomal genes enhance replication (e.g., the siderophore aerobactin facilitates multiplication of *Shigella* within tissues), increase bacterial resistance to nonspecific defense mechanisms (e.g., somatic antigens), or prevent killing by phagocytic cells (e.g., superoxide dismutase).[5] *S. dysenteriae* serotype 1 can increase severity of illness through expression of Shiga toxin, which contains an enzymatically active (A) subunit and five cell-binding (B) subunits.[7] The A subunit irreversibly inhibits mammalian protein synthesis by cleaving an *N*-glycosidic bond at adenine 4324 in the 28S ribosomal RNA, blocking elongation factor 1–dependent binding of aminoacyl transfer RNA to the ribosome. Five identical copies of subunit B bind to globotriaosylceramide, the cell receptor glycolipid.

Chromosomal genes also act by regulating expression of genes on the *Shigella* virulence plasmid. The *malA* gene product functions in the inner membrane as a sensor for the high osmolarity of the colonic contents in the primate intestine, inducing expression of plasmid invasion genes. The chromosomal keratoconjunctivitis provocation gene *(kcpA)* is responsible for movement of *Shigella* in the cytoplasm. The *virR* regulatory loop gene responds to conditions outside the bacteria by inhibiting expression of the invasive phenotype at 30°C.

All virulent *Shigella* species contain a 120- to 140-megadalton (i.e., 200- to 220-kilobase) plasmid.[3,8] As with the chromosomal genes, plasmid genes are involved in regulatory functions, invasion, or intercellular spread; *virF* governs the plasmid virulence regulon by directly activating transcription of two other gene loci, *virG* and *virB*. The latter locus then activates invasion plasmid antigens ipaABCD. The *ipaABCD* genes are highly conserved in *Shigella* invasion plasmids.[2,3] These proteins are the dominant virulence plasmid antigens recognized during the humoral immune response to *Shigella*. Intracellular and intercellular bacterial spread is encoded by *virG*, which has a sequence of repeating motifs in its amino terminus that is involved in polymerization of actin monomers to provide the force to propel *Shigella* within the cytoplasm and into adjacent cells.

This model explains the histologic observations of early neutrophil efflux in colonic crypts and bacterial invasion. The desquamation, ulceration, and formation of microabscesses in the colonic mucosa inhibit absorption of water, with production of stools that are frequent and scanty and that contain blood, inflammatory cells, and mucus. Invasion beyond the mucosa to the bloodstream seldom occurs.

Although mucosal secretory immunoglobulin (Ig) A antibodies develop against the virulence plasmid invasion antigens (ipaABCD) after natural infection, immunity is serotype specific. It is unclear why some people infected with *Shigella* remain asymptomatic.[9] Cellular immunity and cytokine production develop during acute illness. IL-1α, IL-1β, tumor necrosis factors (i.e., TNF-α and TNF-β), IL-4, IL-8, IL-6, and transforming growth factor-β are induced, whereas interferon γ is suppressed.[10,11]

Pathology

Shigella primarily affects the colon.[12] Macroscopically, the affected mucosal surface is edematous and erythematous, covered by a layer of gray mucopurulent exudate with various degrees of ulceration and hemorrhage. Microscopic examination typically reveals hyperemia, edema, and neutrophil infiltration of the colonic mucosa. In early stages, the surface epithelium can be reduced in height and infiltrated with neutrophils. As disease progresses, epithelial cells detach from the edematous lamina propria, leaving microulcerations. With advanced disease, large numbers of lymphocytes and plasma cells can be seen in the lamina propria. At the base of deep necrotic, ulcerated mucosa, a thick pseudomembrane forms, composed of neutrophils, erythrocytes, fibrin, and desquamated epithelial cells. Crypt abnormalities include a marked reduction of goblet cells and hyperplasia of epithelial cells, crypt abscesses, and distention due to exudates. Aphthoid ulcers form over lymphoid aggregates.

In small blood vessels near the lamina propria, pathologic changes include hyperemia, edema, focal hemorrhage, and swelling of endothelial cells. In some cases, thrombosis of blood vessels in the lamina propria and submucosa is associated with widespread necrosis of colonic mucosa. The pathophysiologic basis for the initial watery diarrheal presentation may be related to enterotoxin production, but it has not been fully elucidated.

Epidemiology

The number of annual cases of shigellosis in the United States reported to the Centers for Disease Control and Prevention (CDC) varied from 7746 in 2012 to 22,625 in 2008, with an incidence of 3 to 13 cases per 100,000 people in the general population.[13–15] However, there is substantial underreporting, and the numbers are estimated to be 20 times higher. The highest risk is for children between the ages of 1 and 4 years (particularly children 12 to 36 months), followed by children 5 to 9 years of age.[13,15] Large childcare-associated outbreaks are common and are difficult to control (see Chapter 3).

In the United States, the seasonality of shigellosis has changed from a peak in summer to a high incidence in the late summer and fall.[13] In developing countries with tropical climates, *Shigella* infection is common throughout the year, but higher isolation rates occur during the summer and rainy seasons.

The prevalence of *Shigella* serotypes varies over time and geography. *S. sonnei* is the predominant serotype (~80% of *Shigella* isolates) in developed countries and is increasing in prevalence in developed and developing countries.[3,13,15] In developing countries, *S. flexneri* is still most common, with occasional outbreaks caused by *S. dysenteriae* serotype 1.[16,17]

Shigella are hardy organisms that can be recovered for up to 6 months from contaminated water samples maintained at room temperature.[18] Organisms can survive for up to 30 days in foods such as milk, whole eggs, oysters, shrimp, and flour. *Shigella* can be isolated from toilet surfaces in homes of patients with dysentery and from the fingers of patients who use toilet paper. The ability to survive coupled with a low infectious dose explains contagion. Most cases of shigellosis probably result from person-to-person transmission of small inocula through the fecal-oral route. There is a high risk of spread within families, in childcare centers, in custodial care institutions, in internment camps, and among men who have sex with men.

Water and food are responsible for outbreaks of shigellosis in military camps, cruise ships, community gatherings, and restaurants. In the United States, 58% of the reported *Shigella* outbreaks were restaurant-associated, including large outbreaks with commercially prepared foods distributed in multiple states.[19] Foods usually consumed raw were implicated in 24% of the outbreaks and infected food handlers in 23%.[19] Water plays a major role in transmission in developing countries, as does overcrowding and unsanitary conditions.

Healthy people who become infected with *Shigella* can shed organisms for up to 1 month; appropriate antibiotic treatment reduces the period of excretion to a few days.[18] Malnourished children shed the organism for prolonged periods as a result of their inability to eliminate the organism or to prevent reinfection. In patients with acquired immunodeficiency syndrome (AIDS), prolonged, relapsing, symptomatic shigellosis and lengthy carrier states have been described despite proper treatment.

Clinical Manifestations

Uncomplicated Shigellosis

In adult volunteers, the first symptoms of shigellosis usually occur within 12 to 48 hours of exposure, but symptoms can be delayed for up to 1 week. In mild infections, the only complaints may be watery or loose stools for a few days, with minimal or no constitutional symptoms.[18] In contrast, typical disease in children includes acute onset of high fever, malaise, abdominal cramps, and copious watery diarrhea followed by resolution or heightened toxicity, nausea and vomiting, and passage of frequent, scanty, mucoid, bloody stools associated with abdominal pain and tenesmus.[18,20] Some children have bloody mucoid diarrhea from the onset of illness. Physical findings usually include fever (≥38.5°C), general toxicity, mild dehydration, lower abdomen tenderness, and increased bowel sounds. Rectal examination elicits severe pain. In most cases, symptoms resolve without antimicrobial therapy within 1 week; however, therapy shortens clinical illness and fecal excretion of organisms.

Complications of Shigellosis

The main complications of shigellosis include dehydration due to fluid loss through diarrhea and vomiting, electrolyte imbalance (including hyponatremia and hypokalemia, commonly observed with *S. dysenteriae*), and less commonly, hypoglycemia due to failure of glycogenolysis and gluconeogenesis, especially in young infants.[18,20] Hypoglycemia and hyponatremia have been associated with a higher risk of death.[20] Protein-losing enteropathy can contribute to poor nutrition. In malnourished children with chronic diarrhea or frequent relapses, rectal prolapse can be observed.[20] Hemolytic uremic syndrome is a major complication of infections due to *S. dysenteriae* serotype 1, caused by Shiga toxin production and damage to vascular endothelium.[20]

Bacteremia.

Severe colitis and ulceration can result in loss of the mucosal protective barrier and resulting bacteremia.[21,22] Although *Shigella* bacteremia is rare in developed countries, a study in Bangladesh found that 4% of patients with shigellosis were bacteremic.[21] In this setting, bacteremia was more common in malnourished infants and was associated with significant mortality. *S. dysenteriae* is more commonly associated with bacteremia, disseminated intravascular coagulation, endotoxic shock, and death than other *Shigella* species. However, in one case series of 15 children with *Shigella* bacteremia in Israel, most of the patients were infants with failure to thrive, 87% of the isolates were *S. flexneri,* and there were no isolates of *S. dysenteriae* serotype 1 and no deaths.[23] In patients with AIDS, shigellosis is more common, more severe, and more often associated with bacteremia. After *Shigella* infections, other enteric gram-negative bacilli can cross the damaged mucosa and cause bacteremia.[24,25]

Surgical Complications.

A review of 57 published cases of surgical complications of shigellosis in children over a 40-year period categorized the complications in four groups: intestinal obstruction (53%), appendicitis with or without perforation (28%), colonic perforation (17%), and intra-abdominal abscesses (2%). Thirteen children (23%) died, often despite antimicrobial therapy.[26]

Extraintestinal Infections

Extraintestinal infections caused by *Shigella* spp. are rare. Vulvovaginitis and urinary tract infections are well documented and often result in delayed diagnosis and inappropriate treatment.[27,28,29] Eye infections include keratitis, conjunctivitis, iritis, and iridocyclitis.[26]

Neurologic Symptoms.

In series of hospitalized children with *Shigella* infections, 10% to 45% have neurologic symptoms, including seizures, lethargy, confusion, hallucinations, and headache.[20,30,31] However, neurologic symptoms are overrepresented in hospitalized patients because seizures often are the indication for admission, and in outpatient-based studies, seizures are uncommon. Neurologic symptoms can precede the onset of diarrhea and can suggest a central nervous system intoxication or infection. Cerebrospinal fluid usually is normal; mild lymphocytic pleocytosis (≤12 cells/mm^3) has been observed.[30]

The pathogenesis of *Shigella*-induced neurologic symptoms is not understood fully. Clinical and complementary studies in a murine model documented the role of bacterial components, host inflammatory mediators (e.g., TNF-α, IL-1β, nitric oxide), and brain edema.[32,33] Most children recover completely with no residual neurologic deficit, although studies conducted in Bangladesh found altered consciousness, seizures, and dehydration to be unfavorable prognostic signs.[20,34,35] Fatalities sometimes occur early in the course of illness among children who lack significant dehydration or septicemia but demonstrate stupor, coma, hyperpyrexia, shock, convulsions, and decorticate or decerebrate posturing due to cerebral edema. This Reye-like syndrome may be the most common cause of death from shigellosis in developed countries.[36] *S. flexneri* and *S. sonnei* are the most frequently associated species. This fulminant toxic encephalopathy (called Ekiri syndrome in Japan) has a poor prognosis.[31,36,37] Hypocalcemia may play a role in pathogenesis.[20,36]

Musculoskeletal Symptoms.

A study of 278 patients with shigellosis and 597 controls found that 7% of the patients had reactive arthritis.[38] An additional 2% had other musculoskeletal symptoms, including tendinitis, enthesopathy, or bursitis. Only a single control subject had reactive arthritis. Human leukocyte antigen (HLA) B27 was positive in 36% of the patients with reactive arthritis.[38] Reiter syndrome (i.e., arthritis, urethritis, and conjunctivitis) was reported mainly in adults.

Neonatal Shigellosis.

Shigellosis in neonates and young infants has several unique features. Neonatal shigellosis is uncommon, accounting for only 0.6% of cases in children younger than 10 years of age.[39] This finding may be explained by maternal protective factors that pass through the placenta or by breastfeeding. Conversely, complications, including dehydration, hypothermia, septicemia, meningitis, rectal prolapse, toxic megacolon, and colonic perforation, are more common in infants than in older children; paradoxically neonates often have a shorter duration of diarrhea.[40–43] The mortality rate for infants younger than 3 months of age who were hospitalized with shigellosis was at least double that of older children. Risk factors associated with poor outcome include ileus, hypoproteinemia, gram-negative bacteremia, and hyponatremia.[43]

Laboratory Findings and Diagnosis

The differential diagnosis for watery diarrhea associated with fever due to *Shigella* includes viruses and other bacteria (e.g., *Salmonella, Campylobacter, Yersinia enterocolitica, Clostridium difficile, E. coli, Aeromonas, Plesiomonas*). For patients with clinical dysentery, *Entamoeba histolytica, Balantidium coli,* and noninfectious diseases (e.g., inflammatory bowel disease, allergic proctitis in infancy) also should be considered.

The peripheral white blood cell count in bacillary dysentery can show a dramatic left shift, but this is not consistently found. Microscopic or macroscopic fecal blood and fecal leukocytes are each detected in approximately 70% of cases of *Shigella* infection; both occur in 50% of cases.[44] Although seen more commonly in shigellosis than in other types of bacterial enteritis, findings of fecal blood and leukocytes are signs of colitis due to any cause.

Stool culture to isolate *Shigella* is the basis for diagnosis. However, culture requires several days of incubation, the sensitivity is only 72% to 80%, the organism may not survive transport to the laboratory, and the culture result can be negative for children who have received antimicrobial therapy. Matrix-assisted laser desorption/ionization-time of flight mass spectrometry (MALDI-TOF MS) can shorten the time of *Shigella* identification.[45] Studies showed that polymerase chain reaction (PCR) testing of stool specimens increased diagnosis by 50% compared with culture, with possible simultaneous identification of other enteric pathogens.[46–49] Immune assay with monoclonal antibodies to the IpaC protein detected *Shigella* spp. and enteroinvasive *E. coli* with high sensitivity and specificity.[18] Serology has little value in the diagnosis of acute infection.

Treatment

Rapid correction of fluid and electrolyte deficits, early reinstitution of feeding, and continual replacement of ongoing losses are key elements of therapy.[50] Oral rehydration is the treatment of choice, although patients in shock or coma and those with ileus should be treated with intravenous replacement of fluids and electrolytes.

Appropriate antimicrobial therapy of shigellosis shortens the duration of fever, diarrhea, and fecal excretion of the pathogen (thereby reducing infectivity) and reduces the risk of complications.[18,50,51] Empiric antimicrobial treatment is recommended for patients with colitis or dysentery until culture results are available. Lack of response to therapy or an inability to confirm infection should prompt collection of stool specimens for a second culture and consideration of other possible diagnoses.

Antimicrobial resistance of *Shigella* spp. is increasing worldwide and susceptibility testing of all isolates is recommended.[16,52,53] According to the US National Antimicrobial Resistance Monitoring System for Enteric Bacteria, 67% of *Shigella* isolates were resistant to trimethoprim-sulfamethoxazole, 34% to ampicillin, and 6% to nalidixic acid; resistance was very low to ceftriaxone and ciprofloxacin.[54] Most resistance is plasmid mediated and easily transferable among bacteria. Reduced susceptibility or resistance to azithromycin (i.e., minimal inhibitory concentration [MIC] of 16–32 and ≥32 μg/mL, respectively) has been reported in the United States, Europe, and Asia.[54–57] During 2010–2012, the resistance rate in Asia and Africa to ceftriaxone, cefotaxime, and ceftazidime were 14%, 23%, and 6%, respectively; the rates in Europe and America were less than 1%.[58]

The empiric antimicrobial regimen is determined by host factors, severity of illness, local resistance patterns, and history of travel to an area of frequent resistance. Parenteral antibiotic therapy is recommended for children with proven or suspected shigellosis who have underlying immune deficiency or suspected bacteremia and for those who are unable to take oral medications. A third-generation cephalosporin, preferably ceftriaxone, typically is used empirically because of the excellent clinical and microbiologic response and unlikely resistance (Table 147.1).[50,59,60] Susceptibility results should be used to tailor therapy. In one study, a single dose of ceftriaxone showed bacteriologic failures, but a 2-day course was as effective as a 5-day course, and it can be used when there is a good clinical response, no extraintestinal infection, and no underlying immune deficiency.[60]

TABLE 147.1

Antibiotic Therapy for Children With Suspected or Proven Shigellosis[a]

Drug[b]	Dosage
Cefixime	8 mg/kg/day PO once daily
Ceftriaxone	50 mg/kg/day IV or IM in one dose daily (maximum 1.5 g/day)
Trimethoprim-sulfamethoxazole[c]	10 mg/kg/day (TMP) PO in two divided doses (maximum 320 mg TMP/day)
Ampicillin[c]	100 mg/kg/day IV or PO in four divided doses
Azithromycin	12 mg/kg (maximum 500 mg) on the first day, then 6 mg/kg (maximum 250 mg) for 4 days

[a] Therapy is given for a total of 5 days. Susceptibility test results are used to tailor therapy.

[b] Ciprofloxacin or other fluoroquinolones may be appropriate.

[c] Resistance is common.

IM, intramuscular; IV, intravenous; PO, by mouth; TMP, trimethoprim.

Oral trimethoprim-sulfamethoxazole should be used only for patients who are infected with a susceptible organism or people who have acquired infection in a locale with low resistance. For patients infected with an ampicillin-susceptible, trimethoprim-sulfamethoxazole–resistant organism, ampicillin can be given (see Table 147.1). Cefixime was clinically effective in children infected mostly with *S. sonnei* but showed a relatively high bacteriologic failure rate and was less effective in adults with severe shigellosis caused mostly by *S. dysenteriae* and *S. flexneri*.[61,62] A 2-day course of cefixime was less effective than 5 days.[63] Azithromycin was effective in adults with shigellosis.[64]

In an open, randomized study of children, azithromycin and cefixime had similar clinical efficacy, but azithromycin had a better bacteriologic response.[65] Azithromycin was superior clinically and microbiologically to nalidixic acid in an outbreak of shigellosis in children.[66] Azithromycin is usually recommended as the first-line oral empiric antibiotics for suspected or proven shigellosis in children.

In some settings, antimicrobial resistance patterns leave only fluoroquinolones as a feasible option.[67] Ciprofloxacin (10 mg/kg every 12 hours for 5 days, maximum single dose of 500 mg) is effective treatment, as are ofloxacin and gatifloxacin, although experience in children is limited, and resistance, related mainly to international travel, is well documented.[68]

With appropriate antibiotic therapy, clinical improvement is expected within 1 or 2 days. If there is no improvement by 72 hours of therapy, antimicrobial resistance, extraintestinal complications, or other diagnoses should be suspected.[18,69] Antimicrobial therapy for children with mild disease or children who have recovered by the time the result of a positive *Shigella* culture becomes available is unlikely to affect the clinical course and is therefore controversial. However, antibiotics do shorten fecal excretion and reduce the spread of this highly contagious bacterium, and treatment is recommended for children who are hospitalized, live in institutions, attend childcare centers, or are immunologically compromised.

Antimotility agents should be avoided in cases of shigellosis and other infectious causes of colitis.[70] Data suggest that these drugs prolong symptoms and shedding of the organism. In countries where vitamin A deficiency is common, a single oral dose of vitamin A (200,000 IU) in addition to antimicrobial therapy reduces severity of the illness.[71] Zinc supplementation (20 mg/day, elemental) in Bangladeshi children shortened the duration of the acute disease, promoted weight gain, and improved the immune response.[72,73] A diet rich in animal proteins given for 21 days after completion of antimicrobial therapy for shigellosis resulted in significantly greater height gains in Bangladeshi children.[74]

Prevention

The best strategy to prevent shigellosis in young children is prolonged breastfeeding.[75,76] Specific protective antibodies in the milk of women living in endemic areas decrease the severity of infection in infants.[77,78] Clean running water and appropriate sanitation are crucial. For toddlers and older children, good hygiene practices are helpful but are difficult to implement. Adults involved in food preparation should be instructed in proper hand hygiene technique.[79,80]

Symptomatic children with stool cultures positive for *Shigella* should be excluded from group childcare until treatment is initiated, the diarrhea has resolved, and depending on local regulations, until stool cultures are negative for *Shigella*. In addition to standard precautions, contact isolation is recommended for children hospitalized with shigellosis. Fly control also has been suggested to aid control of spread.

Despite continuing efforts and substantial progress, a *Shigella* vaccine is not available commercially. Several strategies for vaccine development are under study.[81] Lipopolysaccharide-based conjugate vaccines showed minor adverse reactions, a good immune response, and promising efficacy in children.[82–84] Antibiotic prophylaxis against shigellosis usually is not recommended, although for certain brief, high-risk exposures (e.g., travel of immunocompromised child to endemic region), prophylaxis may be reasonable. Appropriate antibiotic treatment of shigellae shortens the duration of excretion and thereby decreases secondary spread to close contacts, especially in settings such as group childcare.

Key Points

Epidemiology, Clinical Manifestations, and Management of Shigella Infections

Epidemiology

- Peak incidence is in children 1 to 4 years of age.
- Because of the low infectious dose, direct person-to-person transmission through the fecal-oral route is most common, especially among young children and in childcare settings.
- Transmission can occur by contact with contaminated environmental surfaces and by consumption of contaminated food or water.

Clinical Features

- Incubation period is 24 to 48 hours but can be as long as 1 week.
- Acute onset of diarrhea (often with blood or mucus) manifests with fever, nausea, vomiting, and abdominal cramps.

- Dehydration and electrolyte imbalance are the most common complications, especially in very young children.
- Extraintestinal complications are uncommon and occur more frequently in neonates or immunocompromised children.

Management

- Mainstay is replacement of fluid and electrolyte losses, preferably by oral rehydration solutions.
- Appropriate antimicrobial therapy shortens the duration of diarrhea, fever, and fecal shedding (thereby reducing infectivity) and apparently reduces the risk of complications.
- Empiric antibiotic therapy should be based on local resistance patterns.
- In most locations, the preferred empiric oral and parenteral antimicrobial agents are azithromycin and a third-generation cephalosporin, respectively.
- No vaccine is available.

Yersinia Species

Theresa J. Ochoa, Miguel O'Ryan

Yersinia species are bacteria in the family Enterobacteriaceae. Of 15 species of *Yersinia*, only *Yersinia enterocolitica*, *Y. pseudotuberculosis*, and *Y. pestis* are human pathogens. *Y. enterocolitica* and *Y. pseudotuberculosis* are enteropathogens transmitted by consumption of contaminated food or water and cause gastrointestinal syndromes that can develop into fatal septicemia in immunocompromised people. *Y. pestis* is the cause of plague that most commonly manifests in the bubonic or primary septicemic forms after the bite of an infected flea or direct contact with infected animal tissues.

Description of the Pathogens

Yersinia are pleomorphic, bipolar-staining, gram-negative coccobacilli. They are aerobic or facultatively anaerobic, non–spore-forming bacteria that ferment glucose, are oxidase negative, and reduce nitrates to nitrites. Species are differentiated by a variety of traits, such as production of urease (*Y. pestis* is negative), motility (*Y. pestis* is nonmotile at 25°C and 37°C), ornithine decarboxylase (*Y. enterocolitica* is positive), and rhamnose (*Y. pseudotuberculosis* is positive) and by several carbohydrate fermentation reactions (*Y. enterocolitica* is positive).

Pathogenesis

Yersinia can survive in a large variety of environmental reservoirs (e.g., soil, plants, insects) and in warm-blooded animals (e.g., rodents, pigs, humans). Despite differences in their mode of entry into the host, clinical manifestations, and disease severity, all three pathogenic *Yersinia* species have a common tropism for lymphoid tissue.

Virulence factors shared by the three species include factors that promote serum resistance, coordinate gene expression, and facilitate iron acquisition. All have a virulence plasmid (pYV) encoding for a type III secretion system (TTSS), which translocates a set of Yop effector proteins into the host cell and are essential for sustained bacterial replication in host tissue. The pYV plasmid differentiates pathogenic from nonpathogenic strains. Adhesins (i.e., Ail, YadA, YadB, YadC, Pla, and pH6 antigen) mediate pathogen-host interactions. Although most bacterial multiplication occurs in the extracellular space, there is evidence that the three pathogenic *Yersinia* species survive and multiply within macrophages, especially during the early stages of colonization.[1–5]

Some virulence genes are unique to a single species. For example, *Y. enterocolitica* has a chromosomal gene that encodes for a guanylate cyclase–stimulating enterotoxin structurally related to the heat-stable enterotoxin produced by enterotoxigenic *Escherichia coli*. *Y. pseudotuberculosis* produces a superantigenic toxin (YPM) that plays a role in systemic infections and a chromosomally encoded PhoP/Q system that regulates survival and growth in macrophages. Highly pathogenic *Y. enterocolitica* and *Y. pseudotuberculosis* harbor the chromosomal high-pathogenicity island, which encodes the siderophore yersiniabactin for iron capture.[5] *Y. pestis* has three main virulence plasmids: pYV, which encodes the TTSS and toxins; pFra, which codes for a capsule that confers resistance to macrophages; and pPla, whose main product (Pla) has protease and plasminogen activator effects.[6–8]

Yersinia Enterocolitica

Epidemiology

Yersiniosis due to infection with *Y. enterocolitica* is a zoonotic gastrointestinal disease in humans. *Y. enterocolitica* can be isolated from a variety of domestic and wild animals (e.g., pigs, cattle, sheep, goat, rabbits, dogs, cats, wild boars, small rodents). Pigs are considered to be the main reservoir of human pathogenic strains. People who eat or handle pork are at risk for illness, and pork intestines (i.e., chitterlings) are a documented source of infection.[9] Eating food prepared from raw products or treated sausage and contact with domestic animals are the main risk factors for sporadic yersiniosis in children.[10]

Milk and other dairy products, even if pasteurized, can sometimes be the source of outbreaks because organisms proliferate at refrigerator temperatures, and low levels of contamination can lead to substantial risk. Refrigerated stored blood is a source of transfusion-acquired illness.[11] Contaminated water can also be a source of infection. Familial and nosocomial spread of *Y. enterocolitica* suggest that person-to-person transmission occurs.

Human infections are more common in cooler climates and tend to occur in winter months. Most reported cases have been from Canada, Europe, and the United States. From 1996 through 2009, the average annual incidence of *Y. enterocolitica* infection in the United States was 0.5 cases per 100,000 people. The rate was highest among African Americans (0.9 per 100,000) but decreased over time from 3.9 to 0.4 cases per 100,000 people. The largest decline occurred in African American children younger than 5 years of age, from 41.5 cases per 100,000 children in 1996 to 3.5 cases per 100,000 children in 2009.[12]

In the European Union, yersiniosis ranks third among reported bacterial zoonoses after campylobacteriosis and salmonellosis. Germany accounts for more than one half of yersiniosis cases reported in Europe.[13] From 2001 through 2008, the average annual incidence of *Y. enterocolitica* infection in Germany was 7.2 cases per 100,000 people, with an incidence of 58 cases per 100,000 children younger than 5 years of age and 108 cases per 100,000 infants.

Clinical Manifestations

Enteric Disease

Y. enterocolitica most commonly causes enterocolitis associated with fever, abdominal pain, vomiting, and diarrhea that contains mucus and gross blood. This presentation occurs most frequently for children younger than 5 years of age. During the first 3 months of life, enteritis can be complicated by bacteremia in up to 28% of cases.[14–16] The relative frequency of specific symptoms may vary by strain biotype/serotype.[13,17] Acute infections cause considerable burden of illness; more than one fourth of patients require hospitalization, and diarrhea commonly persists for more than 2 weeks and occasionally for several months.[18] Untreated people shed organisms for several weeks.

Between 20% and 50% of children with *Y. enterocolitica* infection have bloody diarrhea compared with less than 10% of adolescents and adults. Older children can have mesenteric lymphadenitis (i.e., pseudoappendicitis) or terminal ileitis with fever, abdominal pain, right lower quadrant tenderness, and leukocytosis. Abdominal complications of *Y. enterocolitica* enteric infection include intestinal perforation, peritonitis, intussusception, toxic megacolon, mesenteric vein thrombosis, chronic ileitis, and gangrene of the bowel wall.

Extraintestinal Manifestations

Bacteremia is the major complication of *Yersinia*-associated enteric infection in young children and people with iron overload syndromes, including those undergoing frequent transfusions and chelation therapy, due to sickle cell anemia, β-thalassemia, aplastic anemia, cirrhosis with hemochromatosis, or malignancy and those undergoing long-term hemodialysis and receiving oral iron supplementation.[9,19–23] Less common extraintestinal manifestations include chronic infection with prolonged fever, granulomatous hepatitis, multiple liver and spleen abscesses, acute and chronic pancreatitis, acute pharyngitis, meningitis, osteomyelitis, pyomyositis, myocarditis, endocarditis, conjunctivitis, pneumonia and pleural empyema, urinary tract infection, and renal abscess.

Dermatologic manifestations include cellulitis, abscess, erythema nodosum, erythema multiforme, and cutaneous vasculitis. In adults, the most common complications of enteric infection are postinfectious sequelae, such as erythema nodosum, arthralgia, arthritis, and uveitis.[18] Polyarthritis occurs primarily in people with major histocompatibility class 1 antigen HLA-B27. Although joint swelling can persist for several months, the long-term prognosis is usually benign.[24,25] Chronic inflammatory bowel disease also has been associated with *Y. enterocolitica* infection.[26]

Laboratory Findings and Diagnosis

Fecal leukocytes are common in patients with colitis. *Y. enterocolitica* can be isolated from stool and sometimes from mesenteric lymph nodes or peritoneal fluid specimens from children who have undergone appendectomy. *Y. enterocolitica* grows on all commonly used enteric media. Cold enrichment in phosphate-buffered saline or other selective enrichment media are useful for recovery of *Y. enterocolitica.* Cefsulodin–irgasan–novobiocin (CIN) agar, which is selective for the growth of *Yersinia,* is preferred for isolation from fecal samples. Growth of pathogenic *Yersinia* can require up to 4 weeks of incubation.[27]

Yersinia organisms are coccobacillary and exhibit bipolar staining in blood agar. Stored samples or cultures grown on more restrictive media show morphologic variation with Gram stain. Avirulent strains are pyrazinamidase positive and fail to autoagglutinate; virulent strains stain with crystal violet and Congo red binding assays.

Y. enterocolitica species are divided into six biotypes (i.e., 1A, 1B, and 2–5), which include several serotypes. Most human pathogenic *Y. enterocolitica* strains are biotype 4, serotype O:3. Serotypes most commonly associated with disease in North America are different from those identified in Europe. Serologic responses can be used as evidence of infection when culture results are negative and a compatible syndrome is identified.

Titer determinations are available through commercial laboratories for the most common serotypes, but results should be interpreted with caution. Children younger than 1 year of age are less likely to develop a serologic response than older children. Cross-reactions with *Brucella abortus, Morganella morganii, Salmonella* species, *Bartonella henselae, Chlamydophila pneumoniae, Rickettsia rickettsii,* and *Borrelia burgdorferi* and persistence of titers for several years after *Y. enterocolitica* infection limit the usefulness of serodiagnosis. Using antibodies raised against the recombinant attachment-invasion locus (Ail) protein, detected by indirect enzyme immunoassay and Western blot immunoassay, can aid in identifying pathogenic *Y. enterocolitica* strains.

Several molecular techniques have been developed to identify *Y. enterocolitica* DNA in clinical, food, and environmental samples.[28–30] The detection rate of pathogenic *Y. enterocolitica* in clinical specimens is higher using polymerase chain reaction (PCR) than culture, but results must be interpreted with caution when the sample is from a nonsterile site.

Treatment

The benefit of antibiotics for management of immunocompetent people with *Yersinia* enterocolitis has not been established conclusively. Infected patients with abdominal pain and mesenteric adenitis usually are treated. Patients who are immunocompromised and patients with extraintestinal dissemination should be treated with antibiotics. *Y. enterocolitica* usually is susceptible in vitro to trimethoprim-sulfamethoxazole, chloramphenicol, fluoroquinolones, aminoglycosides, tetracycline, piperacillin, and extended-spectrum cephalosporins and resistant to most penicillins and first-generation cephalosporins.

If septicemia develops during desferrioxamine treatment in patients with iron overload states, chelation should be stopped temporarily. Antibiotic therapy has no beneficial effect on postinfectious syndromes.

Prevention

Outbreaks of illness due to *Y. enterocolitica* often are foodborne and should receive prompt and thorough investigation. Recall of suspected contaminated items can abort an outbreak. Careful attention to appropriate cooking practices in handling of pig products, especially intestines, should decrease the risk associated with these food products. Consumption of uncooked meats should be avoided, and meat should not be refrigerated for prolonged periods before consumption because *Y. enterocolitica* growth can be enhanced at refrigerator temperatures. No vaccine against *Y. enterocolitica* is available, although several candidates are under evaluation.

Key Points

Epidemiology, Clinical Manifestations, Diagnosis, and

Management of *Yersinia enterocolitica* and *Yersinia pseudotuberculosis* Infections

Epidemiology

- Yersiniosis is a zoonotic gastrointestinal disease.
- Contact with pork is a risk factor.
- Infections tend to cluster during winter months.
- Highest incidence
  - *Y. enterocolitica*: children <5 years of age
  - *Y. pseudotuberculosis*: children 5 to 15 years of age

Clinical Manifestations

- Most commonly
  - *Y. enterocolitica:* febrile enterocolitis with or without blood in stools
  - *Y. pseudotuberculosis:* pseudoappendicitis and less commonly Kawasaki-like illness
- Most serious complication: bacteremia mainly in infants and immunocompromised children

Diagnosis

- Stool culture using selective enrichment media
- Mesenteric lymph node or peritoneal fluid culture in children undergoing surgery
- PCR assays are available for clinical samples, food products, and

environmental samples.

Treatment

- Benefit of antimicrobial treatment is not established conclusively for immunocompetent children.
- Antimicrobial therapy should be used for immunocompromised patients with enterocolitis and patients with extraintestinal infection.
- Trimethoprim-sulfamethoxazole, chloramphenicol, fluoroquinolones, aminoglycosides, tetracycline, piperacillin, and extended-spectrum cephalosporins are usually active in vitro.
- Mortality rate for *Y. pseudotuberculosis* septicemia is 75%, irrespective of antimicrobial use.

Yersinia Pseudotuberculosis

Epidemiology

Y. pseudotuberculosis is distributed worldwide in animals, including rodents, birds (e.g., turkey, duck, geese, pigeons, canaries), rabbits, deer, and farm animals. Infection can follow exposure to well and mountain water. The organism was originally described as causing tuberculosis-like lesions in guinea pigs. Household pets often are the source of infection for children. *Y. pseudotuberculosis* also can be transmitted through food products, and outbreaks have been linked to pasteurized milk, lettuce, and carrots.[31,32]

As with *Y. enterocolitica,* infections in humans cluster in colder months. Human infections are most common among children between 5 and 15 years of age, with a threefold male predominance. Although the organism has a worldwide distribution, most cases have been reported from Europe. From 1996 through 2007, the average annual incidence of *Y. pseudotuberculosis* infection in the United States was 0.04 cases per 1 million people.[33] Compared with *Y. enterocolitica, Y. pseudotuberculosis* infects older individuals, who are more likely to require hospitalization for invasive infection. Patients with iron overload are at increased risk for infection, although this seems to be a less common risk factor than for *Y. enterocolitica* infections.

Clinical Manifestations

Y. pseudotuberculosis causes acute gastroenteritis and mesenteric lymphadenitis, often accompanied by fever and abdominal pain. The most common clinical syndrome is pseudoappendicitis, which is characterized by abdominal pain, right lower quadrant tenderness, fever, and leukocytosis. Less commonly, *Y. pseudotuberculosis* can mimic Kawasaki disease and has been implicated as a possible cause.[34–37] Yersinia has also been associated with intussusception, mainly in children.[38] Septicemia or extraintestinal spread of *Y. pseudotuberculosis* is uncommon and primarily has been reported in patients with underlying conditions such as cirrhosis, malignancy, diabetes, aplastic anemia, thalassemia, iron overload, and human immunodeficiency virus (HIV) infection.

Acute renal failure with interstitial nephritis is a complication in up to 14% of patients with *Y. pseudotuberculosis*, although prognosis is usually good.[39,40] *Y. pseudotuberculosis* infection occasionally leads to postinfectious sequelae such as reactive arthritis and erythema nodosum. Reactive arthritis and severe clinical outcome have been particularly associated with *Y. pseudotuberculosis* serotype O:3.[40]

Laboratory Findings and Diagnosis

Stool cultures of individuals with *Y. pseudotuberculosis*–associated pseudoappendicitis commonly are negative even though intestinal infection must have preceded spread to mesenteric nodes. Culture of mesenteric nodes removed at appendectomy can be positive. Cold enrichment of stool cultures and use of CIN agar appears to enhance recovery of *Y. pseudotuberculosis*. Identification of *Y. pseudotuberculosis* from food products and environmental sources using biochemical reactions can be misleading, and serotyping or molecular methods for virulence determinants should be used.[41]

Although 21 serotypes of *Y. pseudotuberculosis* have been identified, 80% of human cases are caused by serotype O:1. Several PCR assays have been developed to identify *Y. pseudotuberculosis*

DNA in clinical, food, and environmental samples, alone or in conjunction with genes for *Y. enterocolitica* or *Y. pestis*.

Treatment

Recovery from *Y. pseudotuberculosis* infection can occur without specific therapy. *Y. pseudotuberculosis* is usually susceptible to ampicillin, aminoglycosides, cephalosporins, trimethoprim-sulfamethoxazole, tetracycline, and chloramphenicol. Optimal antibiotic treatment of the rare patient with septicemia is unclear. The mortality rate for *Y. pseudotuberculosis* septicemia is 75% despite the use of an antimicrobial agent effective in vitro.

Prevention

There is no practical way to prevent sporadic cases of this rare disease. Outbreaks can be managed through careful epidemiologic investigation and intervention. Case contacts are usually at low risk and should not receive prophylactic antibiotics. Several candidate vaccines are under evaluation.

Yersinia Pestis

Y. pestis evolved from *Y. pseudotuberculosis* sometime during the past 20,000 years. Documented plague pandemics occurred during the 6th century (i.e., Justinian Plague) and the 14th century (i.e., Black Death). A third, ongoing pandemic began in the mid-19th century in China. India suffered an estimated 6 million deaths between 1900 and 1909, and Vietnam accounted for approximately 80% of the world's cases between 1965 and 1975. Since the 1990s, African countries (i.e., Madagascar, Congo, and Tanzania) have accounted for more than 90% of cases worldwide.[42–44] Although the severity of these pandemics has decreased due to improved sanitation and use of antibiotics, cases still occur, although mainly in underdeveloped regions.

Epidemiology

Plague is a zoonotic infection that is primarily maintained in rodents and their fleas. Animal reservoirs include rats, rabbits, prairie dogs, bobcats, coyotes, ground squirrels, rock squirrels, and wild mice.[45] Humans are incidental hosts primarily infected through a flea bite or direct contact with animal tissues.

The oriental rat flea *(Xenopsylla cheopis)* is the most efficient vector among many fleas capable of transmitting plague. A blood meal containing the bacillus clots in the flea's gut and causes intestinal obstruction. When the flea continues to feed, it regurgitates organisms into the victim's skin. Cases of human infection often occur after large numbers of infected rats have died, forcing fleas to seek other hosts. Primary pneumonic plague occurs after inhalation of respiratory droplets from a human or animal with pulmonary infection. Although primary pneumonic plague is rare, *Y. pestis* is a category A bioterrorism agent because of its potential to be spread by aerosol.

Plague occurs worldwide with enzootic foci in parts of Africa, Asia, and the Americas. Since 2000, approximately 22,000 cases of plague and 1600 deaths have been reported to the World Health Organization, with more than 95% occurring in countries in sub-Saharan Africa.[46] An upward trend in the incidence was observed starting in 2005, with a global average of 2083 cases reported annually.[47]

In the United States, a total of 1006 human plague cases were reported from 1900 through 2012, including 468 cases since 1965, with a median of 8 cases per year.[48] Since 1965, 88% of US cases have been reported from four states: New Mexico, Arizona, Colorado, and California. The median age of patients was 28 years (range, <1–94 years), and 268 (57%) were male. Although 54% (198 of 370) of patients were white, 33% (123 of 370) were Native American. The route of infection was unknown in 238 (51%) of cases, but 101 (22%) had a known flea bite, and 120 (33%) had contact with an infected animal. The peak onset was in July.

Plague has been associated with occupations and outdoor activities likely to bring people into contact with animals and fleas.[48,49] Occasionally, fleas of a pet dog or cat are the source of infection. Cats can develop symptomatic plague and spread infection through biting, scratching, or coughing. Similarly, dogs can develop moderate to severe illness or die as a result of infection; 62 confirmed cases of canine plague were identified from 2003 to

2011 in New Mexico.[50] An outbreak of four human pneumonic plague cases with dog-to-human transmission was reported in Colorado in 2014.[51]

Clinical Manifestations

Clinical syndromes associated with *Y. pestis* infection are bubonic, septicemic, pneumonic, and meningeal plague. Asymptomatic infections also occur.

Bubonic Plague.

Bubonic plague is the most common form of plague. Symptoms appear 2 to 10 days after a flea bite and are characterized by exquisitely tender, nonfluctuating lymphadenitis (i.e., bubo) in regional lymph nodes draining the bite area. A papule, vesicle, or ulcer at the inoculation site develops in approximately 25% of cases. The skin may show insect bites and scratch marks, but there is no associated ascending lymphangitis. Localized cellulitis or abscess at the flea bite site is rare. In 90% of cases, the bubo is unilateral and can reach up to 10 cm in diameter; suppuration, sometimes with drainage, occurs in approximately 20%.

Although the onset of fever usually coincides with lymphadenitis, it can precede the bubo by several days. Bacteremia usually is associated with high fever accompanied by chills, headache, malaise, anorexia, vomiting, myalgia, and prostration. Complications include endotoxic shock and purpura or gangrene of the extremities due to disseminated intravascular coagulopathy. Bubonic plague was referred to as the Black Death due to the appearance of these lesions. Untreated, it has a mortality rate of approximately 50%.

Septicemia.

Between 10% and 25% of plague cases manifest as primary septicemia with endotoxemia, hypotension, shock, and multiorgan failure without obvious lymph node involvement.[42,49] These patients have a mortality rate that exceeds 30% despite appropriate antimicrobial treatment. Abdominal pain, nausea, vomiting, and diarrhea can occur and confuse the initial diagnostic approach.

Pneumonia.

Pneumonia occurs in less than 16% of cases due to inhalation (i.e., primary plague pneumonia) or hematogenous seeding associated with bubonic or septicemic plague (i.e., secondary pneumonia). Symptoms include chest pain, progressive tachypnea, dyspnea, hypoxia, and productive cough. Sputum can be watery, frothy, blood tinged, hemorrhagic, or purulent. The chest radiograph characteristically shows alveolar infiltrations and extensive bronchopneumonia; cavitation can be seen.

Primary plague pneumonia is characterized by a short incubation period lasting from a few hours to 3 days, with death occurring as early as the first day of symptoms. Secondary pneumonia occurs in 57% of septicemic plague cases and 6% of bubonic cases. Untreated pneumonic plague has a fatality rate of 93%. However, an outbreak in Colorado in 2014 highlighted the potential for milder pneumonic plague in patients taking antimicrobial agents.[51] Pneumonia is the only form of plague with the potential for human-to-human transmission. The possibility of aerosol transmission and the severe disease of pneumonic plague are the basis for considering *Y. pestis* a potential biologic weapon.[42] Rarely, pharyngeal plague can follow direct contact with infectious materials.

Meningitis.

Altered mental status, including lethargy, stupor, and delirium, is common in bubonic plague, but true meningitis tends to be a late complication in patients receiving inadequate treatment. Meningitis is more common in children than in adults and occurs in about 10% of children with plague in the United States[49,52]

Pediatric Considerations.

Among 183 US pediatric plague cases from 1947 to 2001, the primary clinical presentations were bubonic (91%) and septicemic (7%).[49] One third of the bubonic cases developed secondary complications, including bacteremia, pneumonia, or meningitis. Children were more likely than adults to have bubonic plague (91% vs. 79%), develop complications (32% vs. 27%), and die (17% vs. 14%).

Laboratory Findings and Diagnosis

The diagnosis of plague usually is confirmed by culture of *Y. pestis* from blood, bubo aspirate, sputum, or cerebrospinal fluid. *Y. pestis* grows in routine culture media, including blood agar, within 48 hours. Blood cultures are positive for approximately 60% of children with bubonic plague and 100% with septicemic plague. Quantitative blood culture data suggest that a bacterial density greater than 10^2 organisms/mL is associated with an increased risk of hypotension and death. Automated blood culture identification systems can misidentify *Y. pestis*. Isolation of *Yersinia* species from an automated system should be evaluated to determine whether the clinical presentation is consistent with plague.

A positive Wright-Giemsa, Wayson, or fluorescent antibody stain on direct smear or cultures of clinical specimens provides presumptive evidence of *Y. pestis* infection.[53] A single positive serologic test result for *Y. pestis* F1 antibodies by passive hemagglutination or enzyme immunoassay in an unimmunized patient also provides presumptive evidence of plague. A fourfold or greater rise in antibody titers in paired specimens confirms the diagnosis.[42] PCR tests that use structural genes for F1 antigen, plasminogen activator, or murine toxin have been developed and are available in some reference or public health laboratories. Use of a bioluminescent reporter phage that allows rapid detection and antibiotic susceptibility analysis of *Y. pestis* directly from clinical specimens also has been evaluated.[54]

Suspected plague cases should be reported immediately to state and local public health departments. Laboratory personnel should be notified that they will be receiving specimens for evaluation.

Differential Diagnosis

The differential diagnosis of bubonic plague includes streptococcal and staphylococcal lymphadenitis, tularemia, and cat-scratch disease.[49] Septicemic plague, especially in patients with purpura and peripheral gangrene, can be confused with meningococcemia or with sepsis due to other gram-negative pathogens. Common causes of community-acquired pneumonia, tularemia, and hantavirus infection should be considered in the differential diagnosis of pneumonic plague.

Treatment

Y. pestis from human cases have been susceptible universally to β-lactam agents, cephalosporins, carbapenems, tetracycline, aminoglycosides, chloramphenicol, and quinolones.[55] Most isolates are resistant to colistin, polymyxin B, and macrolides, including clarithromycin. Plasmid-mediated multidrug resistance has been described.[56] In many countries, intramuscular streptomycin (20 to 30 mg/kg/day in 2 doses for 7 to 10 days) is the drug of choice for treating plague. Gentamicin, alone or in combination with tetracycline or doxycycline, appears to be equally effective and is an alternative choice.[57]

In a randomized, controlled trial of bubonic plague, gentamicin and oral doxycycline were equivalent; however, it is unclear whether these results can be extrapolated to pneumonic plague.[58] Trimethoprim-sulfamethoxazole is approved by the US Food and Drug Administration (FDA) for the treatment of plague but has higher failure rates and should not be used as first-line therapy for bubonic plague or as monotherapy for septicemic or pneumonic plague.

Fluoroquinolones have been shown to be highly effective in animal and in vitro studies, and the FDA has approved levofloxacin for the treatment of plague. Streptomycin and ciprofloxacin have superior efficacy in vitro against intracellular *Y. pestis*, which is important for the initial phase of infection.[55] In a murine model, the combination of ciprofloxacin and gentamicin was more effective than gentamicin monotherapy to eradicate *Y. pestis* from the lymph node.[59] Chloramphenicol (75 to 100 mg/kg/day) is the drug of choice for plague meningitis, but levofloxacin and other fluoroquinolones with good cerebrospinal fluid penetration should be considered as an alternative therapy.

Fever typically resolves an average of 6 days (range, 1–15 days) after initiation of effective antimicrobial therapy. Relapse after completion of therapy is rare despite the fact that organisms occasionally can be recovered from buboes late in therapy. Intravenous fluids for correction of shock and dehydration usually are required as part of initial management of plague. Corticosteroid therapy is not indicated, and heparin has no proven value for treating associated disseminated intravascular coagulation.

The case-fatality rate ranges from 50% to 90% for untreated bubonic plague and approaches 100% for untreated septicemic and pneumonic plague. With effective antibiotic therapy, the case-fatality rate can be as low as 5% for bubonic plague but remains at 30% or higher for septicemic plague.[60] Patients with pneumonic plague who do not receive therapy within 18 hours of onset of respiratory symptoms are unlikely to survive.

Y. pestis is considered a category A bioterrorism agent.[61,62] Doxycycline or ciprofloxacin is recommended for mass treatment or prophylaxis after a potential bioterrorism event. Children exposed to patients with pneumonic plague or aerosolized *Y. pestis* can receive prophylaxis with doxycycline (2 mg/kg twice daily), trimethoprim-sulfamethoxazole (4 to 6 mg/kg of the trimethoprim component twice daily), ciprofloxacin (15 to 20 mg/kg twice daily), or chloramphenicol (25 mg/kg every 6 hours) for 7 days.[63,64]

Prevention

People living in plague-endemic areas should take measures to decrease rat and flea exposures. Use of an insect repellent containing *N,N*-diethylmethyltoluamide (DEET) applied to the legs and ankles is helpful if exposure is likely. Care in handling of dead animals is important. Insecticides and rat control are useful in the prevention of murine plague. Flea control for pet dogs and cats also is important. Public health officials should be notified when a case of plague is diagnosed to assist in managing environmental reservoirs and vectors.

Spread of pneumonic plague is best prevented by early diagnosis, initiation of appropriate therapy, and strict isolation (including droplet precautions) for patients in whom plague is suspected for several days after initiation of appropriate therapy. Contacts of individuals with plague pneumonia should receive tetracycline, doxycycline, or ciprofloxacin prophylactically for 7 days. Animal studies suggests that imipenem may be used for prophylaxis of *Y. pestis* aerosol exposure.[65] Microbiology laboratory personnel should be alerted when receiving samples possibly containing plague bacillus to exercise extreme caution in handling.

In experimental mouse models, maternal antibodies induced by the plague vaccine can be transferred to the newborn through the placenta and lactation. This suggests that passive immunization could be an effective countermeasure against plague during an epidemic.[66]

Live, attenuated and killed whole-cell vaccines against *Y. pestis* have been available for many years, but they have several shortcomings, including unproven effectiveness, and they are not licensed for use in the United States. Several other vaccines are under development, including live, attenuated; DNA; and subunit vaccines (i.e., F1 and LcrV antigens).[67,68] The potential use of *Y. pestis* for bioterrorism emphasizes the need to develop more effective vaccines against airborne infection.

Key Points

Epidemiology, Clinical Manifestations, Diagnosis, and Management of *Yersinia pestis* Infection

Epidemiology

- *Y. pestis* causes *bubonic or septicemic plague* when acquired through a flea bite.

- Plague occurs largely in poor populations in contact with rodents, particularly in endemic countries of Africa, Asia, and the Americas.

Clinical Manifestations

- Bubonic plague
  - Most common form of plague: symptoms appear 2 to 10 days after a flea bite
  - Symptoms: bubo (exquisitely tender, nonfluctuating lymphadenitis), high fever, headache, malaise, anorexia, vomiting, myalgia, and prostration
  - Complications: endotoxic shock and purpura or gangrene of extremities

- Septicemic plague
  - Sole clinical manifestation in 10% of plague cases
  - Septicemia symptoms: abdominal pain, nausea, vomiting, hypotension, shock, and multiorgan system failure
  - Pneumonia symptoms: chest pain, progressive tachypnea, dyspnea, hypoxia and productive cough (sputum can be watery, frothy, blood tinged, hemorrhagic, or purulent)
  - Chest radiograph: alveolar infiltrates and extensive bronchopneumonia with or without cavities
  - Aerosol transmission and a high potential for severe disease make *Y. pestis* a potential biologic weapon
  - High lethality if not treated promptly
- Meningitic plague
  - Late complication in patients receiving inadequate treatment for bubonic plague
  - More common in children than adults
  - Symptoms: altered mental status, including lethargy, stupor, and delirium

Diagnosis

- Characteristic bipolar-staining coccobacilli in bubo aspirate, cerebrospinal fluid, or sputum using Wright-Giemsa or Wayson stain

- Routine culture media

- Rapid diagnosis: antigen detection tests and PCR

- Fourfold serum antibody rise is diagnostic

Treatment

- Most strains are susceptible in vitro to β-lactam agents, tetracycline, aminoglycosides, chloramphenicol, and fluoroquinolones.

- Drugs of choice include intramuscular streptomycin and gentamicin alone or in combination with tetracycline or doxycycline or ciprofloxacin.

- Doxycycline or ciprofloxacin is recommended for prophylaxis of contacts.

- Mortality rate is 50% to 100% for untreated plague, 5% for treated bubonic plague, and ≥30% for treated septicemic plague.

Acinetobacter Species

Guliz Erdem, Amy Leber

Microbiology

Acinetobacter species are nonmotile, oxidase-negative, catalase-positive, strictly aerobic, gram-negative coccobacilli. Their inability to ferment glucose or to reduce nitrate distinguishes *Acinetobacter* from the family Enterobacteriaceae. *Acinetobacter* is a genus of opportunistic pathogens within the Gammaproteobacteria class in the family Moraxellaceae along with the *Moraxella*, *Psychrobacter*, and other genera.[1–5]

The more than 40 genospecies in the genus *Acinetobacter* include *Acinetobacter calcoaceticus* (genospecies 1), *A. baumannii* (genospecies 2), *A. haemolyticus* (genospecies 4), *A. junii* (genospecies 5), *A. johnsonii* (genospecies 7), *A. lwoffii* (genospecies 8), and *A. radioresistens* (genospecies 12) (http://www.bacterio.net/acinetobacter.html).[6] Most other genospecies cannot be separated easily with conventional biochemical tests or commercial identification systems. Isolates of *A. calcoaceticus, A. baumannii, A. pitti* (formerly genospecies 3), and *A. nosocomialis* (formerly genospecies 13TU) strains can use glucose oxidatively and often are identified as *A. baumannii* by conventional identification systems.[4,7] These organisms can be reported collectively as *Acinetobacter calcoaceticus–A. baumannii* group organisms, but this classification is suboptimal because of the increased clinical significance of *A. baumannii* in human infections. The use of *A. baumannii* group to refer to *A. baumannii*, *A. pitti,* and *A. nosocomialis* may be the limit of differential identification for most laboratories.

Similarly, non–glucose-oxidizing isolates of *A. lwoffii, A. johnsonii,* and *A. junii* may be reported as nonsaccharolytic *Acinetobacter* spp. Most nonhemolytic, glucose-oxidizing clinical isolates are *A. baumannii*, and most nonhemolytic, non–glucose-oxidizing clinical isolates are *A. lwoffii*. Most hemolytic isolates of *Acinetobacter* spp. are *A. haemolyticus*.[1,2,4,5]

Acinetobacter spp. can be isolated readily from clinical material on blood, on chocolate, and usually on MacConkey agar; some fastidious strains grow poorly or not at all on the latter medium. Colonies first appear as small and nonpigmented on blood and chocolate agars and as colorless, light pink, or purplish growths on MacConkey agar. On Gram stain, *Acinetobacter* spp. are short, plump coccobacilli or rods (sometimes resembling *Moraxella* or *Neisseria* spp.) but distinguished easily by their lack of cytochrome oxidase activity. Some cells from direct staining of clinical specimens or from culture can hold the crystal violet of Gram staining and appear as gram-positive, staphylococcal-like cocci.

Additional nutritional and physiologic tests beyond standard identification systems may be necessary.[4] Matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry has good performance for identification of gram-negative bacilli. However, with current databases, identification of *Acinetobacter* species other than *A. baumannii* does not appear to be reliable.[8–10]

For definitive identification of the *A. baumannii* group, genotypic methods such as amplified ribosomal DNA restriction analysis (ARDRA) of the 16S rRNA gene and amplified fragment length polymorphism (AFLP) are recommended.[6] Whole genome sequencing can be used for accurate genotyping and for investigation of the emergence of antibiotic-resistant strains[11,12] (http://www.ncbi.nlm.nih.gov/genome/browse/). Genotypic identification may further clarify roles of the *Acinetobacter* spp. in human disease.

A. baumanii survives for prolonged periods in healthcare environments, resists inactivation by disinfectants, and acquires resistance to a wide variety of antibiotics. The plasticity of the genome appears to play a major role in the organism's ability to gain and rearrange genes associated with pathogenicity. Data on virulence factors associated with *A. baumannii* and other *Acinetobacter* spp. are limited. Factors include capsular polysaccharides, protein adhesins, proteolytic and lipolytic enzymes, aspects of boil formation, and gram-negative lipopolysaccharide.[2,7] OmpA, an outer membrane porin, has been associated with virulence by several mechanisms, including host cell death through apoptosis and biofilm formation.[13] Reports suggest that ethanol can play a regulatory function in the organism, which is a concern because of the common use of ethanol in clinical care settings.[7]

Acinetobacter strains display a twitching motility, particularly in response to light. Regulation of motility is thought to contribute to the organism's spread over surfaces and may facilitate biofilm formation.[7,14] In addition to OmpA liposaccharide, capsular polysaccharide, phospholipase, penicillin-binding protein 7/8, outer membrane vesicles, and acinetobactin-mediated iron acquisition system have been identified as possible virulence factors.[7]

Epidemiology

Acinetobacter spp. are found in many environmental sources, including water, soil, foods, and arthropods, and they can survive on dry surfaces much longer than other bacteria causing with healthcare-associated infections (HAIs).[15,16] Unlike most other gram-negative bacilli, *Acinetobacter* bacteria can colonize dry and moist areas of healthy human skin. In one study of skin and mucous membranes, up to 43% of nonhospitalized patients were colonized with *Acinetobacter* spp.; *A. lwoffii*, *A. johnsonii*, and *A. junii* were the most common species detected.[17] *A. baumannii* uncommonly colonizes healthy human skin and is recovered infrequently from environmental sources outside the hospital. Its natural habitat has not been determined.[5]

Acinetobacter spp. are opportunists in healthcare and home care settings. In a US and European study, *Acinetobacter* spp. were the eighth most common organism isolated from patients hospitalized with pneumonia between 2009 and 2012.[18] Genospecies of *Acinetobacter* may show geographic variations.[19,20] In one US study conducted between 1995 and 2003, approximately one third of *Acinetobacte*r bloodstream infections (BSIs) were caused by *A.*

nosocomialis or *A. pitti*, and 63% were caused by *A. baumannii*.[21] In a study of *Acinetobacter* spp. BSIs in a children's hospital, the most common species recovered were *A. baumannii* (44%) and *A. lwoffii* (39%).[22] Although *Acinetobacter* spp. frequently are acquired nosocomially, BSIs in children were substantially acquired in the home setting in one study.[22] Most patients had an indwelling central venous catheter, and exposure to water or soil was considered a major risk factor.

The rate of colonization with *Acinetobacter* spp. of the skin, oral mucosa, and gastrointestinal tract increases rapidly after admission to the hospital and particularly to intensive care units (ICUs). Nosocomial outbreaks have been associated with reservoirs such as tap water, sinks, room humidifiers, water baths, air conditioners, tap water aerators, respiratory care equipment, dusty filters, and the skin of healthcare personnel.[23–25] Contaminated parenteral solutions can be a source.[26] Patient-to-patient transmission of *A. baumannii* probably occurs by transient colonization and spread by the hands of healthcare personnel.

Acinetobacter spp. are considered pathogens of low virulence. They cause opportunistic infections only in people with compromised immune status or with an indwelling device, or both. Of the top 10 organisms causing hospital-acquired BSIs in US hospitals from 1995 to 2002, *Acinetobacter* spp. ranked 10th in incidence (0.6 of 10,000 admissions) but second in crude mortality rates (34%).[27]

In two reports from the SENTRY Antimicrobial Surveillance Program on pediatric blood, urine, pulmonary, or wound infections for 1998 to 2003 and for 2004, *Acinetobacter* spp. accounted for 1.8% of all pathogenic isolates.[28,29] Risk factors for *Acinetobacter* infection included the use of intravenous devices and urinary tract catheters, immunosuppression, admission to an ICU or burn unit, respiratory failure at ICU admission, previous antimicrobial therapy, diabetes mellitus, and chronic lung disease.[30–32] In a report of the National Nosocomial Infections Surveillance System of the Centers for Disease Control and Prevention (CDC) for 1992 to 1997, the contribution of *Acinetobacter* spp. to pediatric ICU HAIs was 2% of BSIs, 3% of pneumonia cases, 3% of lower respiratory infections other than pneumonia, and less than 1% of urinary tract or surgical site infections.[33] Other infections included endocarditis, meningitis after neurosurgical infections, and peritonitis.

Acinetobacter spp. can be recovered from cultures of blood or other clinical specimen as contaminating or colonizing organisms. This complicates the interpretation of positive cultures.

Clinical Manifestations

Clinical manifestations of *Acinetobacter* BSIs are not unique. Temperature instability, central apnea, and thrombocytopenia can occur in infants.[26] In a study of 29 episodes of *Acinetobacter* spp. BSIs in children with cancer, 11 episodes were polymicrobial, and only 3 occurred in children with an absolute neutrophil count less than 500/mm^3. Risk of infection was associated with solid tumors, indwelling intravascular catheter, recent chemotherapy treatments, and prior receipt of antimicrobial agents. There were few manifestations of gram-negative septicemia other than fever and malaise, and no child developed septic shock.[34,35]

Although *A. baumannii* was the most prevalent species among nosocomial BSIs in two US studies, *A. pitti* and *A. nosocomialis* accounted for more catheter-related BSIs.[21,36] BSI due to *A. baumannii* is associated with a higher mortality rate than BSIs due to *A. pitti* or *A. nosocomialis*.[37] Crude mortality rates for *A. baumannii* BSIs are 28% to 68%.[7,27] In a pediatric case review, the attributable mortality rate was 14.5%.[38]

In a review of 25 patients, including 5 children with nosocomial meningitis due to *Acinetobacter* spp. after neurosurgery, most patients had fever and signs or symptoms of central nervous system infection.[39] The average cerebrospinal fluid white blood cell count was 5700 cells/mm^3 with 90% neutrophils. *A. lwoffii* was more commonly associated with meningitis than other *Acinetobacter* spp. Risk factors for meningitis in infants included a ventriculoperitoneal shunt, previous neurosurgery, and central nervous system abnormalities.[40] *Acinetobacter* spp. have been associated with pediatric outbreaks, predominantly in neonatal ICUs, involving BSI and meningitis.[38]

Most cases of suspected or confirmed pneumonia due to *Acinetobacter* spp. are HAIs in intubated children. Clinical manifestations are not distinctive. Determining a precise pathologic role is challenging because *Acinetobacter* spp. can be isolated from intubated patients, colonizing the upper respiratory tract and contaminating tracheal aspirates. Quantified recovery of *Acinetobacter* spp. from specimens collected by bronchoalveolar lavage is more meaningful in defining infection. The mortality rate for pneumonia due to *Acinetobacter* spp. in ventilated patients can be as high as 23% to 73%.[41]

Urinary tract and wound infections are relatively uncommon in children and usually occur in patients with hematologic malignancies, neonates, or those with neurologic disorders and bladder dysfunction.[42] The incidence of soft tissue infections appears to be increasing.[2] *A. baumannii* is also an important cause of burn infections.[7] Trauma-associated osteomyelitis has been reported among military personnel.[7] *Acinetobacter junii* is reported as a rare cause of BSI and ocular infection in pediatric patients.[24,43]

Treatment

Antimicrobial susceptibility of *Acinetobacter* spp. varies widely across institutions and countries; however, the emergence of multidrug-resistant strains of *A. baumannii* due to selective antimicrobial pressure and intrinsic resistance mechanisms is a worldwide problem.[44–47] Mechanisms of resistance include production of inactivating enzymes, including broad-spectrum β-lactamases class A, B, C, and D and aminoglycoside-modifying enzymes; alteration of penicillin-binding proteins; alterations of DNA gyrase and topoisomerase IV, the target sites for quinolone antibiotics; ribosomal RNA methylation; decreased permeability of the outer membrane to β-lactam antibiotics; and overexpression of efflux pumps and biofilm formation.[2,45]

All strains of *A. baumannii* harbor chromosomally encoded AmpC-type enzymes, referred to as *Acinetobacter*-derived cephalosporinases, somewhat analogous to the AmpC enzymes found in *Enterobacter* spp. and other Enterobacteriaceae.[1] Overexpression of these enzymes results in resistance to extended-spectrum cephalosporins, but cefepime and carbapenem antibiotics retain activity. A wide variety of extended-spectrum β-lactamases (ESBLs) can be found in *Acinetobacter* spp., and these enzymes appear to be similar to ESBLs found in other Enterobacteriaceae and *Pseudomonas aeruginosa*. Horizontal transfer of resistance islands with many resistance genes and rearrangement of preexisting genes permit *Acinetobacter* spp. to adapt to hospital environments.[48]

In a retrospective UK study, *A. baumannii* carbapenem resistance rates rose from 0% in 1998 to 55% in 2006 among bacteremic patients.[49] In the United States, carbapenem resistance rates of *Acinetobacter* spp. rose from 6% in 1999 to 28% in 2006,[21] which are higher than for other gram-negative bacteria.[50] In a US report on ICU patients in 2011, in vitro susceptibility of *Acinetobacter* spp. was 39% to ceftazidime, 43% to meropenem, 48% to tobramycin, and 37% to ciprofloxacin.[18]

Healthcare-related outbreaks due to carbapenem-resistant strains of *Acinetobacter* spp. are reported increasingly.[45,51] In two pediatric ICUs in Thailand and Greece, 64% and 62% of *Acinetobacter* spp. were carbapenem resistant, respcctively.[52,53]

The β-lactamase inhibitor agent sulbactam and the polymyxin antibiotic colistin have been used with some success in a limited number of nonrandomized clinical trials.[54–59] Sulbactam has both β-lactamase inhibitor activity and direct antibacterial activity against *Acinetobacter* spp. by binding irreversibly to penicillin-binding protein 2. Sulbactam has excellent in vitro activity and is effective in treating *Acinetobacter* infections. In vitro synergy with meropenem also has been demonstrated.[56] Ampicillin-sulbactam is more active than ticarcillin-clavulanate or piperacillin-tazobactam and was more effective than polymyxins for the treatment of infections due to multidrug-resistant (including carbapenem-resistant) *Acinetobacter* spp.[54,55] When active, carbapenems have excellent bactericidal activity. Several uncontrolled studies of intravenous colistin for the treatment of multidrug-resistant *Acinetobacter* spp. infections appear to demonstrate effectiveness and safety.[58,60] Minocycline and tigecycline have in vitro activity against *A. baumannii*, but clinical efficacy data are limited, particularly in pediatrics.[61]

Case reports and small studies suggest that combination antimicrobial therapies such as colistin plus rifampicin and tigecycline plus colistin were effective[62,63] and may be preferred for severely ill patients.[64] Aminoglycosides can be used in combination.[59] Eravacycline is being evaluated as an agent with in vitro activity against *A. baumannii*.[65]

Although disk diffusion and dilution minimum inhibitory concentration (MIC) methods of susceptibility testing are recommended for *Acinetobacter* spp. by the Clinical and Laboratory Standards Institute (CLSI), differences in the categorical interpretations of these two methods against selected β-lactam agents have been reported.[66,67] There also are differences between gradient agar diffusion E-test MIC and broth microdilution MIC for *Acinetobacter* spp. against the polymyxins. There are no CLSI disk diffusion or MIC breakpoints for tigecycline against *Acinetobacter* spp., and only MIC breakpoints are provided for colistin.[66] Discordance in the susceptibilities of carbapenems is increasingly described for imipenem, meropenem, and doripenem.[59]

The available data preclude a firm recommendation for combination treatment or monotherapy for children with resistant infections. Most experts prefer combination treatment for severely ill patients. The use of prolonged infusion β-lactam agents, increased drug doses, and altered routes of administration such as nebulized therapy for pulmonary infections may help treatment of infections due to strains resistant to all available antibiotics.[45,67]

Contaminated indwelling devices should be removed. Prevention of *Acinetobacter* spp. infections requires judicious use of medical devices and antimicrobial agents and meticulous adherence of healthcare personnel to infection control practices.

Acknowledgments

We acknowledge the substantial contributions of D.A. Powell and M.I. Marcon to this chapter in previous editions.

Key Points

Diagnosis and Management of *Acinetobacter* Spp. Infections

Microbiology

- Nonmotile, oxidase-negative, catalase-positive, strictly aerobic, gram-negative coccobacilli

- Good growth on blood, chocolate, and usually on MacConkey agar; *A. calcoaceticus*

- *A. baumannii, A. pitti,* and *A. nosocomialis* use glucose oxidatively and often are identified as *A. baumannii* by conventional systems.

Epidemiology

- Wide variety of environmental sources (e.g., water, soil, foods)

- Survives for prolonged periods in the healthcare environment, resists inactivation by disinfectants, and can acquire multidrug resistance

- Risk factors for infection include the use of intravenous devices and urinary tract catheters, immunosuppression, admission to an intensive care unit (ICU) or burn unit, respiratory failure at ICU admission, previous antimicrobial therapy, diabetes mellitus, and chronic lung disease.

- Bloodstream infection, pneumonia, and meningitis are common.

Diagnosis

- Recovery in culture uses standard laboratory procedures.

- Amplified ribosomal DNA restriction analysis (ARDRA) of the 16S rRNA gene and amplified fragment length polymorphism (AFLP) are techniques used for definitive identification but are not available widely.

- Whole genome sequencing can be used for genotyping and investigation of emergence of antibiotic-resistant strains.

Treatment

- Emergence of multidrug-resistant strains is a worldwide problem.

- Ampicillin-sulbactam and carbapenems can be used if strains are susceptible.

- Combination antimicrobial therapies (e.g., colistin plus rifampicin, tigecycline plus colistin) may be preferred for severely ill patients with resistant strains.

- Duration of therapy for systemic and osteoarticular infections or endocarditis is similar to that for other infectious agents.

Aeromonas Species

Miguel O'Ryan, Yalda C. Lucero

Description of the Pathogen

The genus *Aeromonas* consists of environmental, facultatively anaerobic, gram-negative bacilli that are predominantly motile as a result of a single polar flagellum. Although at least 25 species have been described in this genus, only *A. hydrophila, A. caviae, A. veronii* biovar *sobria, A. dhakensis,* and *A. trota* are relevant human pathogens.[1–6] *Aeromonas* spp. produce oxidase, catalase, nitrate reductase, and an array of exoenzymes. They can display a variety of virulence factors, including heat-stable and heat-labile enterotoxins, lipopolysaccharides, hemolysins, proteases, leukocidin, elastase, fibrinolysin, DNase, lecithinase, lipases, amylase, adhesins, agglutinins, pili, and an array of outer membrane proteins.[1,3] The motility of these species is essential for survival in liquid environments and for colonization of surfaces. Subsequently, other outer membrane proteins, including fimbrial systems, mediate human cell adherence. Some strains are also capable of cell invasion and immune system evasion, thereby favoring invasive disease.[3]

Epidemiology

Aeromonas spp. are ubiquitous and can be isolated from almost any environment. Most environmental isolates come from fresh or brackish water sources; contamination of chlorinated tap water also has been reported.[1,3] *Aeromonas* spp. colonize and can cause disease in cold-blooded animals, including fish, amphibians, and reptiles, which can act as reservoirs.[1,5]

The first report of human *Aeromonas* infection occurred in 1954 in a woman with myositis. In 1961, *Aeromonas* spp. were first isolated from human feces. Since then, *Aeromonas* spp. have been incriminated as agents of gastroenteritis, skin and soft tissue infections, and sepsis and other invasive infections mainly in immunocompromised patients. Infection is most common during warmer months and is acquired through ingestion of contaminated water or food, especially fish, seafood, and vegetables, or by swimming or bathing in contaminated water.[1,5,7,8] Skin and soft tissue infections caused by wild animal bites and leech therapy also have been described.[9,10]

Disease burden is difficult to determine as a result of underreporting and lack of routine diagnosis. Specific diagnostic tests are required to differentiate pathogenic species from normal flora and other pathogenic gram-negative bacilli such as *Vibrio* and *Plesiomonas* spp.[1,7] Asymptomatic fecal carriage is observed in approximately 1% to 2% of healthy people residing in nontropical regions and in up to 27% of healthy adults residing in tropical areas.[11–13] *Aeromonas* spp. have been implicated in 1% to 13% of cases of endemic diarrhea in children and in 2% to 7% of cases of diarrhea in adults.[13] These pathogens also have been associated with approximately 2% of dysentery episodes in developed countries and in 7% to 22% of dysentery episodes in developing countries.[14] Among travelers, 1% to 4% of cases of diarrhea have been attributed to *Aeromonas* species, with a higher incidence in travelers to Southeast Asia.[1,2,13]

A prospective study in 70 hospitals in France identified 78 *Aeromonas* spp. infections over 6 months in 2006; of these infections, 44% were skin and soft tissue infections, 26% bacteremia, 19% gastroenteritis, 6% respiratory tract infection, and 5% miscellaneous.[5]

Clinical Manifestations

Gastroenteritis.

Gastroenteritis is the most common clinical illness attributed to *Aeromonas* infection in humans.[13] Both the small intestine and large intestine can be infected. Self-limited watery diarrhea is the most common presentation, although cholera-like illness has been reported.[1] Fever and vomiting are common in children. One third of patients have dysentery associated with colitis[14,15]; fever and malaise are more common in patients with this presentation. In contrast to other causes of dysenteric bacterial gastroenteritis, stool leukocytes are uncommon. Chronic or intermittent diarrhea lasting for weeks has been described in one third of patients infected by *A. caviae*.[1,15] Reported complications include bacteremia, intussusception, failure to thrive, hemolytic uremic syndrome, and strangulated hernia.[1,16]

Skin and Soft Tissue Infections.

Skin and soft tissue infections comprise the second most common presentation of *Aeromonas* infections; *A. hydrophila* is the predominant species.[5] Major predisposing factors are local trauma occurring in people during recreational swimming, exposure to contaminated water in occupational or recreational activities, and shark or reptile bites. Soft tissue infection also has been reported in patients immersed in water immediately after being burned and, more rarely, after leech therapy or standard medical procedures such as gastrointestinal tract operations.[1,5,9] Cellulitis develops 8 to 48 hours after trauma, eventually followed by rapid spread to deep tissues. The clinical spectrum includes localized skin nodules, soft tissue abscess, furunculosis, ecthyma gangrenosum, bullous cellulitis with crepitance, synergistic necrotizing cellulitis, and myonecrosis.[17] *Aeromonas* soft tissue infection can mimic cellulitis caused by group A streptococcus, *Clostridium* species, and ecthyma gangrenosum caused by *Pseudomonas aeruginosa*.[1,17,18] Immunocompromised patients are at increased risk for bacteremia and sepsis.[19]

Sepsis.

Septicemia is the most serious and life-threatening complication of *Aeromonas* infection. Septicemia occurs primarily in immunocompromised patients, especially people with hematologic malignant diseases, hepatobiliary conditions, and malnutrition.[5,6,20–23] Cases in immunocompetent hosts increasingly are reported, associated with burns, penetrating trauma, and recreational or professional activities with exposure to contaminated water.[1,5] Although most cases are community acquired, nosocomial bloodstream infection (BSI) has been described in oncologic patients.[6] Clinical presentation is similar to that caused by other gram-negative bacilli, including fever (74%–89%), jaundice (57%), abdominal pain (16%–45%), septic shock (40%–45%), and dyspnea (12%–24%). Diarrhea immediately preceding or concurrent with the onset of bacteremia is uncommon (9%–14%). In 60% to 70% of these BSIs, *Aeromonas* is the only bacterium isolated, but the remaining infections occur in association with other organisms such as *Escherichia coli*, *Klebsiella pneumoniae*, and *Staphylococcus aureus*. A secondary focus of infection in ascitic fluid, bile, wounds, or urine can be found in up to 25% of patients.[1,5–7,20,22,24] BSI-associated mortality rates range from 5% to 60%, depending on the underlying condition. Poor prognosis has been associated with altered consciousness, septic shock, underlying liver cirrhosis and cancer, community-acquired focal infection, and persistent or secondary bacteremia.[6,24]

Uncommon Clinical Presentations.

Aeromonas spp. have been rarely associated with a variety of other systemic and local infections including intra-abdominal infections (peritonitis, pancreatitis, cholangitis, hepatic abscesses), pneumonia (aspiration associated with near-drowning episodes), lung abscess, endophthalmitis, tonsillitis, otitis media, urinary tract infection, endocarditis, meningitis, osteomyelitis, pyogenic arthritis, and suppurative thrombophlebitis.[1,5,25–27]

Laboratory Findings and Diagnosis

No pathognomonic clinical laboratory findings are present in *Aeromonas* spp. infections. Gastroenteritis can be associated with abnormalities of acid-base and renal function; white blood cell count and serum C-reactive protein level can be mildly elevated.[1,5] In skin and soft tissue infection, BSI, and other invasive infection, moderate leukocytosis (up to 16,000 cells/mm^3) and a high serum C-reactive protein level are common.[5,22]

Bacterial isolation is essential to support the diagnosis. Stool samples should be transported at room temperature in transport media such as Cary-Blair. Blood and other fluids should be transported and incubated in blood culture bottles. *Aeromonas* spp. grow easily in routine enteric isolation media such as MacConkey, xylose lysine deoxycholate (XLD), Hektoen enteric (HE), *Salmonella Shigella* (SS), and deoxycholate citrate (DC) agar. Because *Aeromonas* are nonlactose fermenting, colonies can be misclassified as normal enteric flora. Use of selective media, such as sheep blood agar containing ampicillin, is recommended. DNase-toluidine blue agar can be used to detect nonhemolytic and ampicillin-susceptible strains, which represent <10% of pathogenic strains. Cefsulodin-irgasan-novobiocin (CIN) agar is more cost-effective because it allows concomitant isolation of *Yersinia* and *Plesiomonas* species. *Aeromonas* agar is a highly selective media that contains irgasan and D-xylose.[1,2] Aeromonads can be differentiated from other gram-negative bacilli by biochemical testing. *Aeromonas* spp. are oxidase positive, indole positive, and urease negative. Oxidase activity helps differentiate *Aeromonas* spp. from Enterobacteriaceae.[1,2] Biochemical tests have limitation for taxonomic classification of aeromonads.

Gene amplification assays have been developed and validated for *Aeromonas* spp. detection, both in clinical and environmental samples, as single pathogen assays or in multiplex tests.[6,28–33] Genotyping by partial sequence analysis of housekeeping genes such as *gyrB, rpoB,* and *rpoD* can be useful for epidemiologic purposes.[6,28,30]

Treatment

Most cases of *Aeromonas*-associated gastroenteritis are self-limited, but appropriate rehydration is important. Data from uncontrolled studies suggest a possible benefit of antimicrobial therapy in shortening the duration of disease.[34] Antibiotics are recommended in patients with dysentery or prolonged diarrhea (>7 days) and for immunocompromised patients. A 3-day course of azithromycin (10 mg/kg/day), ciprofloxacin (15 mg/kg twice a day), or ceftriaxone (50–75 mg/kg/day) is a treatment option for children. In adults, azithromycin (500 mg once a day), ciprofloxacin (750 mg once a day), or levofloxacin (500 mg once a day) can be used.[14]

For skin and soft tissue infections, early diagnosis, aggressive surgical debridement, and parenteral antibiotics are important.[17,19,35,36] BSI should be managed with parenteral antimicrobial therapy and a thorough search for focal infection. Aminoglycosides, fluoroquinolones, trimethoprim-sulfamethoxazole, third-generation cephalosporins, and carbapenems are reasonable empiric therapies for skin and soft tissue infections, BSIs, and other invasive infections.[37,38] However, in vitro susceptibility testing of clinical isolates is important because resistance to multiple agents is described,[6] including penicillin, first- and second-generation cephalosporins, vancomycin, clarithromycin, clindamycin, and carbenicillin.[1,34,39] At least 4 different types of β-lactamases have been reported in *Aeromonas* spp., of which an inducible chromosomal β-lactamase is predominant. Isolates producing extended-spectrum β-lactamases occur sporadically.[37] Although induction of β-lactamases in the clinical setting is rare, clinicians should monitor the patient for potential relapse when using cephalosporins for a serious *Aeromonas* infection.[5,6,19]

Prevention

Aeromonas spp. are present in fresh and brackish nonprocessed water, fish, shellfish, meat, and fresh vegetables. Avoiding ingestion of natural source water and contaminated food, especially by infants and immunocompromised patients, is important. Cooking food products eliminates these organisms. Cross-contamination after processing should be avoided. Food products should be handled appropriately (e.g., storing raw and processed products separately and chilling until consumption). *Aeromonas* infections also should be considered in the management of traumatic wounds sustained in or exposed to aquatic natural environments and in near-drowning events.[1]

Key Points

Diagnosis and Management of *Aeromonas* Species Infection

Microbiology

- Environmental, facultatively anaerobic, gram-negative bacilli
- Display a variety of virulence factors including a single polar flagellum, adhesins, enterotoxins, and exoenzymes
- Motility, cell invasion, and immune system evasion relevant pathogenic mechanisms

Epidemiology

- *Aeromonas* spp. colonize and can cause disease in cold-blooded animals (fish, amphibians, and reptiles), which can act as reservoirs.
- Transmission to humans is most common during warmer months, through ingestion of contaminated water or food, or by swimming or bathing in contaminated water.
- Can cause gastroenteritis, skin and soft tissue infections, and sepsis and other invasive infections predominantly in immunocompromised patients

Diagnosis

- Grow easily in routine enteric isolation and blood culture media (can be missed or misclassified as normal enteric flora nonlactose fermenting; selective media, biochemical tests, and PCR assays are useful for their identification)
- Identification from a clinically relevant sample essential for diagnosis and susceptibility tests
- PCR techniques for single-pathogen or multiplex assays available for *Aeromonas* spp. detection in clinical and environmental samples

Treatment

- Most cases of gastroenteritis are self-limited, and hydration is the priority in management.

- Antimicrobial therapy (azithromycin, fluorquinolone or ceftriaxone) is recommended in patients with dysentery or prolonged diarrhea (>7 days) and for immunocompromised patients.

- Skin and soft tissue infections, bloodstream infections, and other invasive infections require parenteral antibiotics (aminoglycoside, fluoroquinolone, trimethoprim-sulfamethoxazole, third-generation cephalosporin, or carbapenem). Skin and soft tissue infections require aggressive surgical debridement.

Prevention

- Appropriate handling and processing of potentially contaminated food and water

- Avoidance of contamination of traumatic wounds or burns with nonprocessed water

PCR, polymerase chain reaction.

Less Commonly Encountered Nonenteric Gram-Negative Bacilli

Michael T. Brady, Amy Leber

Microbiology and Epidemiology

Several genera of nonglucose-fermenting gram-negative rods are infrequent opportunistic human pathogens. As a group, most are nonfastidious, aerobic, catalase-positive organisms; motility, oxidase activity, and growth on MacConkey agar are variable. Those organisms that grow on MacConkey agar typically produce colorless colonies. Identification of organisms has depended on phenotypic and biochemical characteristics. Matrix-assisted laser-desorption ionization–time of flight (MALDI-TOF) mass spectrometry has been used more recently.[1–3] The utility of MALDI-TOF mass spectrometry improves as databases are expanded. Taxonomy continues to undergo significant changes based on DNA homology studies and 16S ribosomal RNA (rRNA) gene sequencing. The organisms are widely distributed in natural environments including plant material, soil, and water, as well as in the environment in healthcare facilities. Some species can colonize mammalian mucosal surfaces.[1,2,4] In many ways, these organisms resemble *Pseudomonas* spp. including *Pseudomonas aeruginosa.* This chapter focuses on select taxonomic family groups not discussed in other chapters.

Pseudomonadaceae.

Certain organisms in the family Pseudomonadaceae have been reclassified. An earlier classification scheme grouped the pseudomonads into 5 homology groups based on similarities in 16S rRNA gene sequence. At present, only the former members of rRNA homology group I are retained in the amended genus *Pseudomonas.* The most common *Pseudomonas* spp. isolated from human clinical specimens are the fluorescent pseudomonad group organisms, *P. aeruginosa, P. putida,* and *P. fluorescens*. *P. stutzeri, P. mendocina, P. alcaligenes, P. pseudoalcaligenes, P. luteola,* and *P. oryzihabitans* are isolated less frequently (see Chapter 154). Both *P. luteola* (formerly *Chryseomonas luteola*) and *P. oryzihabitans* (formerly *Flavimonas oryzihabitans*) are catalase-positive, oxidase-negative, motile, gram-negative bacilli that form yellow-pigmented, often wrinkled colonies on blood and MacConkey agar. The negative oxidase reaction of these organisms is unique among *Pseudomonas* spp. *P. luteola* can be differentiated from *P. oryzihabitans* on the basis of its ability to hydrolyze esculin and orthonitrophenyl-β-D-galactopyranoside.[4]

rRNA homology group II organisms now are designated *Burkholderia* spp., *Ralstonia* spp., *Cupriavidus* spp., *Pandoraea* spp., and related organisms in the family Burkholderiaceae; rRNA homology group III contains *Comamonas* spp., *Delftia* spp., and *Acidovorax* spp. in the family Comamonadaceae; rRNA homology group IV pseudomonads are now classified as *Brevundimonas* spp. in the family Caulobacteraceae; and rRNA homology group V pseudomonads are now *Stenotrophomonas* spp.[1]

Alcaligenaceae.

Both *Achromobacter* and *Alcaligenes* spp., along with the closely related *Bordetella* spp., currently are grouped together within the family Alcaligenaceae. The clinically relevant *Achromobacter* and *Alcaligenes* spp. include *Alcaligenes faecalis, Achromobacter piechaudii, Achromobacter denitrificans,* and *Achromobacter xylosoxidans.*[2,5] The first 3 organisms listed are asaccharolytic and biochemically are similar to *Bordetella* spp. and *Oligella ureolytica,* also members of this family.[6] *Achromobacter xylosoxidans* is saccharolytic and biochemically is similar to several organisms of uncertain taxonomic position, including *Achromobacter* groups B, E, and F and *Ochrobactrum anthropi*; the former *Achromobacter* groups A, C, and D are biovars of *O. anthropi*.[7] *Ochrobactrum* spp. have been placed in the family Brucellaceae. The genus *Oligella* contains 2 species of clinical significance, *O. urethralis* and *O. ureolytica*.[6] *O. urethralis* (formerly *Moraxella urethralis*) is nonmotile, shares several characteristics with *Moraxella* spp., and is thought to be a commensal of the genitourinary tract. *O. ureolytica* is motile and biochemically is similar to *Bordetella bronchiseptica,* including the property of rapid hydrolysis of urea.

Caulobacteraceae.

Several *Brevundimonas* spp. have been named, but only *B. diminuta* and *B. vesicularis* are of human clinical significance. These species currently are placed in the family Caulobacteraceae. All these organisms are aerobic, oxidase-positive, motile, gram-negative bacilli that can be isolated in the laboratory on blood or chocolate agar; most but not all strains also grow on MacConkey agar. Some isolates produce a yellow or tan-brown pigment.

Comamonadaceae.

Current members of the family Comamonadaceae include the following: *Comamonas testosteroni* and *C. terrigena; Delftia acidovorans* (formerly *Comamonas acidovorans*) and *D. tsuruhatensis;* and 3 *Acidovorax* spp.—*A. facilis, A. delafieldii,* and *A. temperans.*

Flavobacteriaceae.

The family Flavobacteriaceae has undergone extensive revision and now contains many genera including *Chryseobacterium, Elizabethkingia, Flavobacterium, Weeksella, Bergeyella, Empedobacter,* and *Myroides. Elizabethkingia meningoseptica* (formerly *Chryseobacterium meningosepticum* and *Flavobacterium meningosepticum*) and *Chryseobacterium indologenes* are the most common human isolates of this group.[1,2,5,6] *E. meningosepticum* produces large, smooth colonies on blood and chocolate agar within

24 hours, but most isolates do not grow on MacConkey agar. Gram stain of agar isolates reveals long, thin rods that can be filamentous. Isolates are encapsulated and produce proteolytic enzymes including elastase, a potential virulence factor. Ribotyping demonstrates heterogenicity among strains of *E. meningoseptica.*[4] Other *Chryseobacterium* spp. produce colonies of similar appearance; some produce yellow-pigmented colonies on blood agar, but pigment production may be negative or weak, except for the deep-yellow pigment produced by *C. indologenes.*[1]

Flavobacterium breve has been reclassified as *Empedobacter brevis.* Organisms formerly classified as *F. odoratum* are now classified as 2 distinct species, *Myroides odoratus* and *M. odoratimimus*. *Weeksella zoohelcum* has been reclassified as *Bergeyella zoohelcum,* and *Weeksella virosa* remains as the single species in the genus. Unlike the other flavobacteria that are environmental organisms, *W. virosa* and *B. zoohelcum* are found on mucosal surfaces of humans and other mammals.[1,2,4,5] Colonies of *W. virosa* are mucoid, adherent to agar, and can develop a tan appearance, whereas colonies of *B. zoohelcum* can be sticky and tan in appearance. Useful tests to differentiate these organisms include the following: hydrolysis of gelatin, starch, and esculin; DNase and urease production; nitrate reduction; and susceptibility to penicillin and polymyxin B.[1,2,4,5]

Methylobacteriaceae.

Methylobacterium spp. and *Roseomonas* spp., members of the family Methylobacteriaceae, are oxidase positive and produce characteristic pink- or coral-pigmented colonies on a variety of media, including blood, Sabouraud, Thayer-Martin, and buffered charcoal–yeast extract agar. These are environmental organisms that also can be found in the healthcare environment. Colonies of *Methylobacterium* spp. generally appear dry, and Gram stain shows large, highly vacuolated, pleomorphic bacilli; growth on MacConkey agar at temperatures higher than 40°C usually is negative. In contrast, colonies of *Roseomonas* spp. are mucoid in culture and show nonvacuolated, coccoid bacilli on Gram stain; these organisms usually grow on MacConkey agar at temperatures up to 42°C.[4]

Rhizobiaceae.

Rhizobium spp. *and Agrobacterium* spp. are members of the family Rhizobiaceae and are natural inhabitants of soil and well-known pathogens of plants. *Rhizobium radiobacter* (formerly *Agrobacterium radiobacter* and *A. tumefaciens*) is the only medically important species in the family.[8] Colonies of the organism can appear mucoid and pink on MacConkey agar, resembling colonies of *Klebsiella* spp.

Sphingomonadaceae.

The family Sphingomonadaceae contains numerous species, but only 2 species are considered to be of human clinical significance, *Sphingomonas paucimobilis* (formerly *Pseudomonas paucimobilis*) and *S. parapaucimobilis. S. paucimobilis* grows slowly and produces yellow colonies; however, in contrast to *Sphingobacterium* spp., most isolates of *S. paucimobilis* are urease negative and susceptible to polymyxin B.[2]

Sphingobacteriaceae.

The family Sphingobacteriaceae contains several former *Flavobacterium* spp., but only 2 species are considered of human clinical significance, *Sphingobacterium multivorum* and *S. spiritivorum. Sphingobacterium* spp. generally are yellow pigmented, urease positive, and resistant to polymyxin B; this last property is shared with *Burkholderia* spp., *Chryseobacterium* spp., and a few other genera of nonfermentative gram-negative bacilli.[2]

Shewanellaceae.

The genus *Shewanella*, family Shewanellaceae, has more than 20 species, but only *S. putrefaciens* and *S. algae* are thought to be of clinical importance. *S. algae* is a halophilic and asaccharolytic organism and thought to be the more common human isolate, whereas *S. putrefaciens* is nonhalophilic and saccharolytic and more commonly isolated from the environment. Among nonfermentative gram-negative bacilli, these organisms have the unique property of producing hydrogen sulfide in Kligler or triple sugar iron agar.[2]

Acetobacteraceae.

Acetic acid bacteria belonging to the family Acetobacteraceae have been associated with human infection relatively recently. Relevant clinical genera in this family include *Asaia, Gluconobacter,* and *Granulibacter*.[2] These organisms oxidize alcohols or sugars, thus producing acetic acid. They are found in soil or associated with plants and have been used to convert wine to vinegar. *Asaia* spp. include a group of pink-pigmented gram-negative rods. Colonies are pale pink with scant to moderate growth on sheep blood agar, and they are oxidase negative. Relevant clinical species include *A. bogorensis, A. lannensis* and *A. siamensis*. *Gluconobacter* are gram-negative, catalase-positive, oxidase-negative rods. *Granulibacter* are oxidase-negative, coccobacillary, gram-negative rods.

Clinical Manifestations and Treatment

As a group, these organisms are opportunistic pathogens that cause relatively few human infections. Most infections occur in people with underlying medical conditions or indwelling medical devices. For many organisms, no standardized methods are available for in vitro antimicrobial susceptibility testing or interpretation of results. Empiric management rests on clinical experience and published reports. In vitro testing should establish antimicrobial minimum inhibitory concentrations to guide definitive therapy. Disk diffusion testing can be unreliable. An in vitro test result of “resistant” indicates a likely treatment failure, but a result of “susceptible” may not predict treatment success. Device removal and surgical debridement when relevant are primary treatments.

Acidovorax, Brevundimonas, Comamonas, and *Delftia* Species

Single cases of *Acidovorax* spp. bloodstream infection (BSI) and implanted port- or catheter-related infections have been reported.[9,10] *Brevundimonas vesicularis* infections in children have included septic arthritis in a healthy toddler,[11] as well as BSIs in a patient undergoing hemodialysis, in a child with sickle cell disease,[12] and in 2 premature neonates.[13,14] Infections with *B. vesicularis* in adults have included infective endocarditis,[15] keratitis after laser surgical procedures,[16] and BSIs following bone marrow transplantation,[17] open heart surgery,[18] and ambulatory peritoneal dialysis.[19] *B. vesicularis* typically is susceptible to meropenem, piperacillin-tazobactam, and aminoglysosides.[20] Susceptibility is less common for ceftazidime and trimethoprim-sulfamethoxazole.[20] *B. diminuta* has been associated with BSI and vascular catheter infections primarily in patients with cancer, peritonitis associated with chronic ambulatory peritoneal dialysis, and cutaneous infections in immunocompetent people.[19,21–22] *Comomonas testosteroni* and *C. kerstersii* infections commonly are polymicrobial and occur most often in the abdomen including following perforation of the appendix.[23,24] *C. testosteroni* was reported to cause catheter-associated BSI, endocarditis, and meningitis in a patient with recurrent cholesteatoma.[25–30] *Delftia acidovorans* has caused catheter-associated BSI, endocarditis associated with intravenous drug use, conjunctivitis, and otitis externa.[31–34] *Delftia tsuruhatensis* has caused catheter-associated BSI.[35] Antibiotic susceptibility of this group of organisms is variable, but most isolates are susceptible to broad-spectrum cephalosporins, carbapenems, and fluoroquinolones. *B. diminuta*, however, is intrinsically resistant to fluoroquinolones,[21] and susceptibility to aminoglycosides is variable.

Achromobacter and *Alcaligenes* Species

Achromobacter and *Alcaligenes* spp. are opportunistic human pathogens causing sporadic cases of pneumonia, septicemia, peritonitis, and urinary tract and other infections.[36–39] *Achromobacter xylosoxidans* and *Alcaligenes faecalis* are the most common isolates and agents of disease, but little is known about factors promoting virulence. Whereas BSI, meningitis, and pneumonia are reported most commonly, sites of isolation also include peritoneal fluid in chronic ambulatory peritoneal dialysis, joint fluid, bone, and urine.[36–40] Infections have been associated with contaminated medical supplies and devices, such as transducers, topical medications, nuclear medicine tracers, deionized water used for hemodialysis, and fluids from incubators and humidifiers.[38,41,42] In patients with cancer, the gastrointestinal tract can be the source of infection.[37] *A. xylosoxidans* has been recovered from blood and cerebrospinal fluid (CSF) of neonates with nosocomial infection, in maternal BSI, and from bone after penetrating nail injury in older children.[36,38,42] Clinical illness resulting from *A. xylosoxidans* BSI is indistinguishable from that of other gram-negative bacilli.[43]

Intravascular catheters frequently are predisposing factors to infection, but neutropenia is not a major risk factor.[37]

A. xylosoxidans and A. faecalis can colonize the respiratory tract of intubated children and patients with cystic fibrosis.[40,44] *A. xylosoxidans* is a "late colonizer" in up to 8.7% of patients with cystic fibrosis and can contribute to exacerbation of pulmonary disease.[45,46] *A. xylosoxidans* has been reported to cause lymphadenitis in patients with chronic granulomatous disease and hyperimmunoglobulin M syndrome.[47,48]

The antimicrobial susceptibility pattern of these organisms is variable.[37,49] Isolates of *A. xylosoxidans* and *A. faecalis* produce several types of β-lactamases that hydrolyze a variety of the penicillins and cephalosporins. Ceftazidime generally retains good in vitro activity against *A. xylosoxidans;* meropenem and trimethoprim-sulfamethoxazole typically also are active. Resistance to aminoglycosides and aztreonam is expected; activity of ureidopenicillins, ticarcillin−clavulanic acid, and the fluoroquinolones is variable. Monotherapy is probably sufficient in most cases of infection, but 2 agents may be required to eradicate the organism in patients with severe, deep-seated infections such as endocarditis. Removal of a contaminated venous catheter or other device often is necessary to clear infections.

Rhizobium radiobacter

Virtually all reported cases of human infections with members of the Rhizobiaceae family are caused by *Rhizobium radiobacter* and have occurred in immunocompromised hosts or in patients with medical devices, especially central venous catheters (CVCs), chronic ambulatory peritoneal dialysis catheters, or implanted biomedical prostheses.[50–58] The ability of this organism to adhere to silicone and other inert surfaces may explain these associations. Approximately 20% of cases of human infections have occurred in people ≤16 years of age. More than 50% of infections required antibiotic therapy and removal of the device for resolution. *R. radiobacter* also has caused native valve endocarditis and urinary tract infection.[50–58]

The antimicrobial susceptibility is variable, and many isolates are multiply resistant because of production of antibiotic-inactivating enzymes. Most strains are inhibited by ceftriaxone (but not ceftazidime), gentamicin (but not tobramycin), trimethoprim-sulfamethoxazole, piperacillin-tazobactam, ciprofloxacin, and carbapenems. Although *R. radiobacter* infections typically are of low virulence, variable antibiotic susceptibility and lack of optimal therapeutic regimens make them difficult to treat.[50–52]

Chryseobacterium, Elizabethkingia, Bergeyella, Weeksella, Myroides, and *Empedobacter* Species

Members of the genera *Chryseobacterium, Elizabethkingia, Bergeyella, Weeksella, Myroides,* and *Empedobacter* spp., all once classified as *Flavobacterium* spp., are responsible for infrequent infections. *Elizabethkingia* (formerly *Flavobacterium*) *meningoseptica* is of greatest medical importance. Although recovered from patients with community-acquired infections, *E. meningoseptica* is most frequently an opportunistic nosocomial pathogen of infants ≤3 months of age, who account for >75% of reported cases.[59,60] *E. meningoseptica* has caused numerous nursery outbreaks of infection, especially BSI and meningitis.[61] Approximately one half of reported cases of meningitis caused by *E. meningoseptica* in neonates have occurred during nursery outbreaks.[62] Outbreaks have been associated with contamination of solutions and equipment in the hospital environment, including containers of antiseptic solutions, vials of intravenous drugs, chlorinated water sources, and respiratory care equipment.[62]

Infants become colonized with *E. meningoseptica* in the nose, throat, or gastrointestinal tract before development of invasive infection. The clinical course of BSI or meningitis is similar to that of infection with other gram-negative bacilli; meningitis can have either an early or a late onset. The onset of disease can be insidious, and CSF evaluation can be unremarkable initially.[61] The mortality rate of neonatal meningitis caused by *E. meningoseptica* is >50%, and survivors frequently have severe neurologic sequelae, including hydrocephalus. Development of hydrocephalus is significantly associated with administration of intrathecal antibiotics or positive CSF cultures for >10 days.[61]

E. meningoseptica rarely causes infection in immunocompetent children beyond the neonatal period, but infections in immunocompromised people occur as outbreaks in intensive care units or as isolated cases; >90% of cases are nosocomially acquired.[60] Pneumonia is the most common infection, accounting for 40% of reported cases. The mortality rate in immunocompromised patients is >60%. Other reported *E. meningoseptica* infections include endocarditis, ophthalmologic infections, cellulitis, pyogenic arthritis related to an elbow joint prosthesis, abdominal abscesses, and burn wound sepsis.[63,64] Prolonged antibiotic therapy may predispose patients to infection.

Although *Chryseobacterium indologenes* is the most common human isolate within this group, recovery of the organism is not always associated with infection. *C. indologenes* primarily causes BSI in immunocompromised patients and in patients with indwelling intravascular devices, but it also has been implicated in cellulitis, bacteremia, pneumonia, meningitis, pyomyositis, and keratitis.[65–69]

Weeksella virosa is recovered primarily from urine and urogenital tract specimens, but its clinical significance is questioned. *Bergeyella zoohelcum* is an inhabitant of the oropharynx of dogs and cats and has been recovered in bite wound infections and in a case of meningitis that followed multiple bites.[70–73] *Bergeyella* sp. was recovered from amniotic fluid of a mother delivering a preterm infant, but its significance was unclear.[74] The 2 current *Myroides* spp., *M. odoratus* and *M. odoratimimus*, are uncommon human isolates from urine, respiratory tract, and rarely blood. *Empedobacter brevis* also is reported rarely as an agent of human disease.

E. meningoseptica and other related species can be resistant to antimicrobial agents routinely prescribed for gram-negative infections including third- and fourth-generation cephalosporins, carbapenems, aztreonam, and the aminoglycosides. *E. meningoseptica*, however, may be susceptible in vitro to agents generally active against gram-positive organisms including rifampin, vancomycin, and clindamycin. Antibiotics with the most consistent in vitro activity against both *E. meningoseptica* and *C. indologenes* are minocycline, rifampin, and levofloxacin. Ciprofloxacin, trimethoprim-sulfamethoxazole, and piperacillin-tazobactam are less active.[60,61,75–78] In vitro test results may not correlate with clinical efficacy. Both *W. virosa* and *B. zoohelcum* are susceptible to a wide variety of antimicrobial agents. Disk diffusion susceptibility testing of *Chryseobacterium* spp. and related agents can be unreliable.[76,77]

Optimal therapy for serious infections, including meningitis, caused by *E. meningoseptica* is not well established. Minimum inhibitory concentrations of vancomycin are high for almost all isolates. A study of 4 *E. meningoseptica* isolates recovered from neonatal CSF demonstrated synergy in vitro between vancomycin and rifampin in 3 of 4 isolates, as well as additive interaction between vancomycin and ciprofloxacin and antagonism between vancomycin and meropenem in all 4 isolates.[79] High-dose vancomycin and rifampin may be the optimal therapy for management of central nervous system infections.[79] Minocycline for patients ≥8 years of age, trimethoprim-sulfamethoxazole, or a fluoroquinolone is a treatment option, based on susceptibility testing, for infections outside the central nervous system.

Methylobacterium and *Roseomonas* Species

Methylobacterium mesophilica and *Roseomonas gilardii* are the most frequently isolated species. Both organisms have been reported as agents of BSI, primarily in association with an indwelling CVC, hemodialysis catheter, and contaminated endoscope. Other reported infections include peritonitis related to chronic ambulatory peritoneal dialysis, septic arthritis, endophthalmitis, cellulitis, bacteremia, keratitis, ventilator-associated pneumonia, and urinary tract infection.[80–90] These organisms generally are susceptible to carbapenems, aminoglycosides, tetracycline, and fluoroquinolones.[91–93] *Roseomonas mucosa* strains typically are more resistant than are strains of *R. gilardii*.

Ochrobactrum Species

Ochrobactrum anthropi is the most common *Ochrobactrum* sp. causing disease. *O. anthropi* colonizes the respiratory tract and wounds and subsequently can cause a variety of opportunistic infections including CVC-associated BSI, prosthetic valve endocarditis, septic arthritis, osteomyelitis, peritonitis, BSI, and meningitis.[52,94–110] Other *Ochrobactrum* spp. including *O. haematophilum* and *O. pseudogrignonense* have been isolated rarely from human clinical specimens.[111] The closely related *Achromobacter*-like groups B, E, and F organisms have been recovered most commonly from blood cultures of patients with CVCs.[112] Most isolates of these *Achromobacter*-like groups and *O. anthropi* are susceptible to aminoglycosides, carbapenems, fluoroquinolones, and trimethoprim-sulfamethoxazole.[113]

Oligella Species

The 2 *Oligella* spp. of clinical significance, *O. urethralis* and *O. ureolytica,* have been recovered primarily from the urogenital tract and rarely as agents of urosepsis or pyogenic arthritis.[114,115] *O. urethralis* has an antibiotic susceptibility pattern similar to that of *Moraxella* spp. Antibiotic susceptibility of *O. ureolytica* is variable.

Pseudomonas luteola and *Pseudomonas oryzihabitans*

Both *P. luteola* and *P. oryzihabitans* are found in natural environments such as soil, water, and damp environments including rice paddies, as well as in the hospital environment in sinks and respiratory therapy equipment. Infections with both organisms are found most commonly in patients with medical devices or immunosuppressive conditions,[116–121] and they include osteomyelitis, peritonitis, endocarditis, meningitis after a neurologic procedure, leg ulcer in a patient with sickle cell disease, endophthalmitis following cataract operation, polymicrobial BSI, cellulitis, abscesses, and wound infections.[122–129]

Published data are insufficient to recommend treatment regimens. *P. luteola* and *P. oryzihabitans* are susceptible to most extended-spectrum penicillins, third-generation cephalosporins, fluoroquinolones, and aminoglycosides, but they usually are resistant to ampicillin and first- and second-generation cephalosporins.[116–119] Because of the low virulence of *P. oryzihabitans,* patients can recover spontaneously from infection after removal of foreign material.[121]

Sphingobacterium, Sphingomonas, and

Shewanella Species

Sphingobacterium multivorum and *S. spiritivorum* are the most commonly recovered species from clinical specimens, usually from blood and urine. Isolates generally are resistant to the aminoglycosides and polymyxins, are susceptible to fluoroquinolones and trimethoprim-sulfamethoxazole, and have variable susceptibility to β-lactam agents.[130–132]

Sphingomonas paucimobilis and other *Sphingomonas* spp. have been recovered from blood, CSF, urine and urogenital sites, and wounds; these organisms have caused sporadic or community-acquired infections including BSI, osteomyelitis, pyogenic arthritis, meningitis, urinary tract infection, and wound infection.[133–139] Infections follow acquisition from the environment or nosocomially from contaminated fluids or equipment.[129–131] A single case of BSI caused by *S. mucosissima* in a patient with sickle cell disease was reported.[139] Most isolates are susceptible to aminoglycosides, fluoroquinolones, and trimethoprim-sulfamethoxazole; susceptibility to β-lactam agents is variable.[134]

Shewanella algae and *S. putrefaciens* have clinical importance. *Shewanella* spp. have been recovered in association with BSI, CVC-associated BSI, ventilator-associated pneumonia, tonsillitis, cerebellar abscess, ventriculoperitoneal shunt infection, peritonitis, osteomyelitis, pyogenic arthritis, and external ear and skin and soft tissue infections following trauma.[140–151] These organisms generally are susceptible to a wide variety of antimicrobial agents, except for first-generation penicillins and cephalosporins.[140–151]

Granulibacter, *Asaia*, and *Gluconobacter* Species

A few acetic acid bacteria have been reported to cause human infections. *Granulibacter bethesdensis* can cause fever and necrotizing lymphadenitis in patients with chronic granulomatous disease.[152,153] Biopsy can reveal necrotizing granulomatous inflammation, negative Gram stain but growth within 3 weeks on Middlebrook 7HII, buffered charcoal–yeast extract, or fungal media. These reported infections required surgical treatment and prolonged antimicrobial therapy for resolution,[152] and recurrence or relapse is possible. *Granulibacter* organisms typically are multiresistant. Susceptibility testing is difficult because of poor growth. Ceftriaxone, aminoglycosides, doxycycline, and trimethoprim-sulfamethoxazole can be active against these organisms in vitro. Ceftriaxone may be the preferred agent.[152] *G. bethesdensis* has been shown to persist in monocytes in patients with chronic granulomatous disease as a result of resistance to oxygen-independent microbicides in monocytes; this organism requires intact reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase for clearance.[154]

Infections with *Asaia* spp. primarily have consisted of catheter-associated BSI, peritonitis related to peritoneal dialysis, and BSI in an intravenous drug user.[155–158] Identification in clinical specimens usually requires 165 rRNA gene sequence analysis. Antimicrobial therapy and catheter removal have been successful as treatment. *Asaia* spp. are multidrug resistant, with susceptibility in reported cases limited to tobramycin and tetracyclines.

Acetic acid bacteria such as *Gluconobacter*, *Acetobacter*, and *Asaia* spp. have been isolated from sputum of patients with cystic fibrosis, in whom a liquid acidic environment likely is relevant.[99,159] The role of these bacteria in clinical symptoms is unclear. Association with intravenous drug abuse may reflect the use of acidic substances (vinegar or lemon juice) to dilute heroin and the possible contamination of compounds used.[158–162]

Key Points

Diagnosis and Management of Less Commonly Encountered Nonenteric Gram-Negative Bacilli

Microbiology

- Nonglucose-fermenting nonenteric gram-negative rods
- Nonfastidious, aerobic, and catalase-positive organisms
- Motility, oxidase activity, and growth on MacConkey agar variable

Epidemiology

- Environmental organisms (plant material, soil, water, and healthcare facilities) that rarely cause infections in normal hosts

- Some species able to colonize mammalian mucosal surfaces

Clinical Manifestations

- Commonly associated with indwelling devices

- May be present in respiratory samples taken from patients with cystic fibrosis during respiratory exacerbations; but role frequently is unclear

Diagnosis

- Organisms recoverable by standard culture methods

- Antibiotic resistance testing required because of the considerable strain susceptibility variation

Treatment

- Empiric antimicrobial treatment should include agents with broad spectrum activity against gram-negative bacilli.

- Definitive therapy is based on antimicrobial susceptibility test results.

Eikenella, Pasteurella, and *Chromobacterium* Species

Guliz Erdem, Amy Leber

Microbiology

Eikenella, Pasteurella, and *Chromobacterium* species display both common and contrasting characteristics of laboratory properties, epidemiology, and clinical presentations. *Eikenella* and *Pasteurella* spp. are nonmotile, whereas *C. violaceum* is motile and less fastidious than the others.

The genus *Eikenella* contains only 1 species, *E. corrodens,* which belongs to the family Neisseriaceae along with the genera *Neisseria* and *Kingella.*[1–4] *E. corrodens* is a small, straight rod that can appear coccobacillary. The organism is oxidase positive and ornithine decarboxylase positive and reduces nitrates to nitrites, but it does not produce catalase, urease, or indole.[1–3] *E. corrodens* originally was thought to be related to the strictly anaerobic bacterium *Bacteroides ureolyticus* (formerly *Bacteroides corrodens*) because of the characteristic "corroding" or "pitting" of the surface of blood or chocolate agar by some isolates, suggesting a preference for anaerobic growth.

The genus *Pasteurella* contains several species of clinical significance and belongs to the family Pasteurellaceae along with the genera *Aggregatibacter, Actinobacillus, Haemophilus,* and *Mannheimia*. Most *Pasteurella* spp. are oxidase and catalase positive, reduce nitrates, and use glucose and a variety of other carbohydrates. The taxonomy of the genus is in flux; currently *P. multocida*, the most important species of human significance, can be separated into the subspecies *multocida, septica,* and *gallicida*. *P. canis*, *P dagmatis,* and *P stomatis* are other species isolated from humans.[1,5–7] Several other *Pasteurella* spp. are rarely if at all associated with human disease.[1,2,6–8] The classification of *Pasteurella* spp. is undergoing revision based on DNA-DNA hybridization studies and ribosomal RNA sequence analysis, and several species, including *P. pneumotropica, P. aerogenes,* and *P. bettyae,* may be reclassified as members of the genus *Actinobacillus* or other genera in the family Pasteurallaceae.[9,10] Organisms formerly classified as *P. gallinarum* now are named *Avibacterium gallinarum,* and some formerly classified as *P. haemolytica* now are named *Mannheimia haemolytica.*

The genus *Chromobacterium* currently contains only 1 species of human significance, *C. violaceum,* and also is placed in the family Neisseriaceae; certain other *Chromobacterium* spp. recovered from environmental sources have been proposed. Most of these organisms are microaerophilic, facultatively anaerobic, somewhat fastidious, gram-negative bacilli that can appear pleomorphic or coccobacillary in direct smears or smears prepared from culture. *C. violaceum* is a long, gram-negative, slightly curved bacillus. *C. violaceum* is positive for catalase, nitrate reductase, and arginine dihydrolase; it grows on sheep blood, MacConkey, chocolate, and Mueller-Hinton agar; and it produces a deep purple pigment (violacein) that can result in black-appearing colonies. The pigment also can be produced during infection, thus resulting in violaceous cellulitis.

Pathophysiology and Epidemiology

E. corrodens is part of the normal flora of the oral cavity, upper respiratory tract, and mucosal surfaces of the gastrointestinal and genitourinary tracts of humans and some mammals.[11,12] From both a clinical and a laboratory diagnostic perspective, it is useful to discuss *E. corrodens* in the context of the so-called HACEK group organisms. This mnemonic stands for *Haemophilus parainfluenzae, Aggregatibacter aphrophilus* (formerly *Haemophilus aphrophilus* and *H. paraphrophilus*), *Aggregatibacter* (formerly *Actinobacillus*) *actinomycetemcomitans, Cardiobacterium hominis, E. corrodens,* and *Kingella kingae* and other *Kingella* spp. As a group, these are slow-growing organisms that often require elevated carbon dioxide concentrations and hemin in the culture medium for optimum growth.[11] HACEK organisms are clinically important in specific disease syndromes, including disseminated diseases, such as subacute bacterial endocarditis and pyogenic arthritis, as well as localized pyogenic diseases of the oral cavity, head, and neck.[12] Compared with the other organisms in the HACEK group, *E. corrodens* is less fastidious and generally is recoverable within 24 to 48 hours on routine blood and chocolate agar media. Because of improvements in composition of broth media and detection techniques, blood cultures from patients with endocarditis suspected to be caused by *E. corrodens* or other HACEK group organisms generally need not be incubated beyond the routine 5 days used in most laboratories.[1–3,13] *E. corrodens* has a lectin-like protein and multiple pilus proteins on the cell surface that may contribute to adherence to mucosal epithelial cells. Some genes coding for pilus proteins share nucleotide homology, and the pilus proteins show amino acid sequence homology with pilin genes and proteins from *Moraxella* spp. and *Neisseria gonorrhoeae.* Other cell surface proteins have the ability to agglutinate red blood cells. The cell wall possesses lipopolysaccharide, and *E. corrodens* can synthesize an extracellular polysaccharide or slime layer. The organism can trigger inflammation in periodontal tissue that can promote periodontitis.[14] Such virulence factors also may play a role in inhibiting phagocytosis or modulating macrophage activity.[2]

Pasteurella spp. are commensals of the upper respiratory tract, with oropharyngeal carriage found in most dogs and cats, including large cats (lions, tigers, panthers), as well as in swine, rats, opossums, rabbits, fowl, and possibly humans.[15] *Pasteurella* spp. are primary pathogens of a variety of animals, and several species can cause various human infections, most commonly associated with animal bites or scratches. In a study of 159 human isolates of *Pasteurella* spp. recovered from dog or cat bites, *P. multocida* subsp. *multocida* accounted for 60% of isolates, *P. canis* for

18%, *P. multocida* subsp. *septica* for 13%, *P. stomatis* for 5%, and *P. dagmatis* for 3%.[7] *Pasteurella* also can be acquired through aerosol inhalation, and differences in the propensity of the 2 *P. multocida* subspecies to cause respiratory tract disease may be present.[16] Although a known animal exposure is present in most human *P. multocida* infections, 5% to 15% of cases of these infections have none. *Pasteurella* spp. generally can be isolated from culture on blood or chocolate agar within 24 to 48 hours of incubation; most strains do not grow on MacConkey agar. Gram stain smears of growth on agar reveal small gram-negative coccobacilli. Biochemical identification of *P. multocida* is straightforward; however, identification of some other *Pasteurella* species can be difficult.[5,8–10] Use of conventional biochemical systems such as Vitek (bioMérieux, Inc., Durham, NC) and also matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry are able to identify *Pasteurella* to the genus level accurately, with MALDI-TOF mass spectrometry better able to give accurate species identification.[17]

Studies of virulence factors of *Pasteurella* spp. have been focused on *P. multocida*, in which virulence can be associated with production of neuraminidase and lipopolysaccharide endotoxin. A dermonecrotic toxin, a known virulence factor in animals, can be detected more commonly in strains isolated from adults with chronic bronchitis than from other sources. The best characterized potential virulence factor is *P. multocida* toxin (PMT), a highly potent mitogen that blocks apoptosis. PMT is thought to be a potential carcinogen, but little evidence exists for its role in human cancer.[18,19]

C. violaceum is a common saprophyte of soil and water, especially in tropical and subtropical areas.[20,21] The organism usually gains entry through the skin to cause localized wound infection, but bloodstream and disseminated infection can occur in patients with select immune dysfunction. *C. violaceum* can be isolated readily from blood, abscess fluid, or purulent drainage, and identification is achievable using commercial systems. *C. violaceum* is included in MALDI-TOF mass spectrometry databases and in the VITEK 2 ID-GNB card.[1,22] Pigmented and nonpigmented strains can have similar pathogenicity and disease severity.[23,24] Several virulence factors have been identified including endotoxin, adhesins, invasins, and cytolytic proteins.[25]

Clinical Manifestations

Most infections caused by *E. corrodens* involve the head, neck, or respiratory tract or are related to human bites or fist-to-mouth injuries.[12,26–29] Localized infections generally are indolent and follow a slowly progressing course, often becoming manifest no earlier than 1 week after injury. *E. corrodens* is a cause in approximately 25% of infections resulting from clenched fist injuries. These slowly evolving infections can lead to complications such as a stiff joint or, rarely, even amputation.[27] Oral contamination can lead to infection of surgical wounds, such as after craniofacial or esophageal reconstruction. *E. corrodens* is prevalent in subgingival plaque of adults with periodontitis.[30] Pleuropulmonary infections also can occur, presumably as a result of aspiration of oral contents or leakage of oral secretions into the pleural space after surgical procedures. In these cases, pneumonia, empyema, or pulmonary cavitation can result.[29–31] *E. corrodens* often is part of a polymicrobial infection, especially with viridans or β-hemolytic streptococci, staphylococci, and oral anaerobic bacteria in human bites, head and neck infections, respiratory tract infections, and hepatic abscesses.[1–3,32–34] *E. corrodens* infections occur in immunocompromised people as well as in people with normal immune function.[35] *E. corrodens* can be found concurrently with *Actinomyces* spp. and may contribute to the pathogenesis of actinomycosis,[1,36] and it has also been implicated with *Actinomyces* spp. in a distinctive clinical infection known as chronic diffuse sclerosing osteomyelitis of the mandible.[36]

E. corrodens also can be recovered from peritoneal cultures after ruptured appendix, gastric operations, traumatic duodenal rupture, gastric cancer, and abscesses of the spleen, liver, and pancreas.[37–39] Other serious *E. corrodens* infections include bloodstream infection (BSI), endocarditis, pyogenic arthritis, spondyloarthritis, chorioamnionitis, neonatal sepsis, neonatal conjunctivitis, orbital infections, meningitis, sinusitis, submandibular abscess, thyroiditis, thyroid abscess, renal abscess, and brain abscess.[28,40–51] Invasion of the central nervous system can occur by extension from periodontal, middle ear, or sinus infections (Fig. 152.1). BSI and endocarditis most often occur in immunocompromised hosts, intravenous drug abusers, and patients with previous cardiac valve damage. Osteomyelitis of the calcaneus has been reported subsequent to penetration of the heel by a toothpick.[27] Injection and fingerstick site abscesses caused by *E. corrodens* have been reported in adolescents with insulin-dependent diabetes mellitus; licking or biting skin or nails could provide an opportunity for the organism to contaminate traumatized skin.[52]

Thompson and K.D. Herzog, St. Christopher's Hospital for Children, Philadelphia.)

Infection with *Pasteurella* spp., most commonly *P. multocida,* generally occurs after an animal bite.[53–55] *P. multocida* is the pathogen in >50% to 75% of infections following a cat bite and in up to 50% of infections following a dog bite[54] (Fig. 152.2). Cat scratches also can be complicated by *P. multocida* infection. Infection can occur after bite injuries from lions, tigers, or other large cats, as well as rats, rabbits, and other animals. Wound infections caused by *P. multocida* typically develop rapidly, within 12 to 24 hours after injury, and manifest with warmth, swelling, redness, and tenderness and with serosanguineous-to-purulent discharge at the site.[53] Regional lymphadenopathy, chills, and fever are common. In a review spanning 10 years, the highest rate of infection occurred in children <5 years of age and in adults >55 years of age.[53] Tenosynovitis and tendon sheath abscess formation, osteomyelitis, and pyogenic arthritis are complications related to deep penetration by the teeth or claws of the animal.[54,56] Preexisting joint disease can predispose patients to pyogenic arthritis.

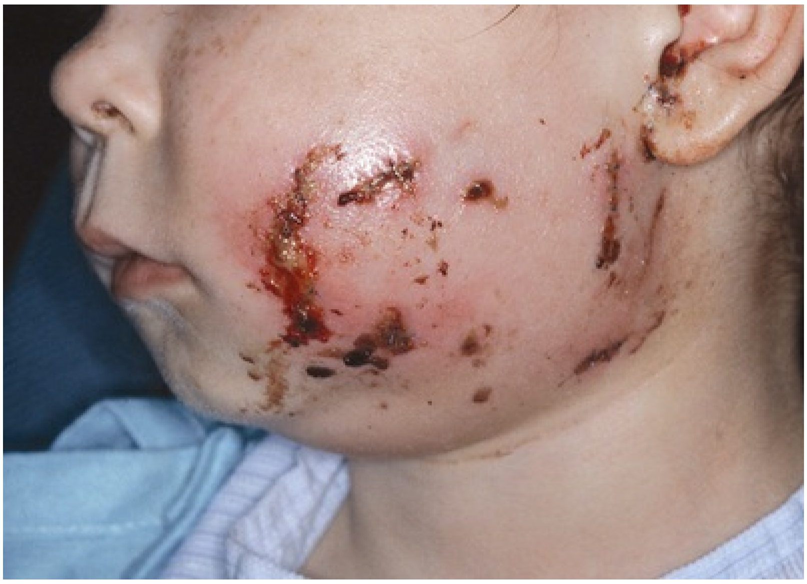

FIGURE 152.2 **A toddler with facial cellulitis caused by *Pasteurella multocida* following a dog bite.** (Copyright by J.H. Brien.)

Some cases of infection with *Pasteurella* spp. occur in people with frequent animal exposure but without a bite or scratch injury. These cases include infections of the upper respiratory tract, soft tissue infection secondary to accidental injury, intra-abdominal infections, meningitis, and bone and joint infections.[54] Pneumonia with or without empyema is rare and occurs chiefly in adults with underlying chronic bronchopulmonary disease. *P. multocida* can cause BSI and meningitis in infants and children, with most cases occurring in infants <12 months of age.[57–60] Exposure to animals was frequently nontraumatic and typically subsequent to a pet dog or cat licking the infant's face. The symptoms of central nervous system infection and abnormalities of cerebrospinal fluid in infected children are typical of bacterial meningitis; however, a mononuclear cell predominance in cerebrospinal fluid has been reported.[58,59,61,62] BSI is documented in approximately 50% of patients with meningitis. Neurologic sequelae are uncommon. Other *P. multocida* central nervous system infections include brain abscess secondary to direct penetration of the brain parenchyma after a dog bite, subdural empyema, and ventriculoperitoneal shunt infections.[61,63]

P. multocida is a rare cause of fetal infection secondary to maternal BSI and invasion through the placenta,[64] although ascending infection also has been postulated.[65,66] This situation is in contrast to fetal infections in animals, in which *Pasteurella* spp. are well-documented causes of septic abortion. Neonatal systemic infection with *P. multocida* has been reported only rarely. The presentation is similar to that of early onset group B streptococcal disease and is characterized by fulminant septicemia with or without meningitis. Neonatal infection usually occurs in the setting of a maternal obstetric complication, including chorioamnionitis, premature onset of labor, prolonged rupture of membranes, postpartum fever, or premature delivery.[67,68] The mortality rate is high, particularly in infants who acquire infection in utero and who are symptomatic at birth. The maternal genital tract is the source of the infection for both infant and mother. Genital colonization is thought to occur as a result of hand inoculation after animal contact.[67,69] Late onset meningitis and cervical spine osteomyelitis were reported in a 20-day-old infant from a household with 2 pet cats.[70] The infection occurred without an obvious history of cat bites, scratches, or licks. Systemic infections are rare in older children and adults.[71,72]

People with underlying abnormalities of host defense, especially liver disease, are predisposed to BSI caused by *P. multocida* infection.[53] Direct trauma from an animal bite or scratch has occurred in some patients, but oropharyngeal colonization secondary to contact with secretions of a pet also can be the source of invasive infection. Septic shock develops in approximately 50% of patients, and the mortality rate approaches 40%. Contiguous spread of infection from liver to lung with involvement of the diaphragm has been reported.[73] *P. multocida* also has been associated with peritonitis secondary to a ruptured appendix or peritoneal dialysis, endophthalmitis after a cat scratch, prosthetic vascular graft infection, and granulomatous hepatitis.[74–76] Urinary tract infection caused by *P. multocida* is rare but has been reported in children with underlying renal disease.[77,78] Repeated catheterization and skin contamination with *P. multocida* can contribute to introduction of the organism into the urinary tract.[77]

Possible horizontal transmission has been reported.[71] A case of *P. multocida* BSI in a patient with Kikuchi disease has been reported, but the relationship between Kikuchi disease and *P. multocida* infection could not be established.[79] Several other *Pasteurella* spp. have been reported as human pathogens. *P. canis, P. dagmatis,* and *P. stomatis* have been associated with wound infections and osteomyelitis after cat or dog bites, as well as with endocarditis, peritonitis, and sepsis in a patient with cirrhosis and with septicemia in a diabetic patient.[80–83] The reservoir of *P. canis* is the oral cavity of dogs, whereas the latter 2 species have been recovered from the oral cavity of both dogs and cats. *P. aerogenes* has been associated with animal bite wounds, urinary tract infection, and peritonitis in humans.[10,84] *P. bettyae* has been recovered from amniotic fluid, blood (usually in the neonatal period), finger lesions, abscesses, wounds following rectal surgical procedures, and genitourinary lesions, particularly Bartholin gland abscesses.[10,85] Peritonitis caused by *P. aerogenes* and *P. pneumotropica* was reported in a patient undergoing peritoneal dialysis following bites by hamsters.[80,86]

C. violaceum is a rare human pathogen but is a common soil and water inhabitant in tropical and subtropical areas; most infections are reported from Southeast Asia.[1,20,21] All cases of infection reported in the United States have been in the southeast, especially Florida, Georgia, Louisiana, and South Carolina. A review of 106 reported cases between 1952 and 2009 showed that 42% of the patients were younger than 10 years of age, and most patients did not have any predisposing factors.[24] Infections occur primarily in boys or men during the summer months and usually involve injury to the skin in association with exposure to soil or water. Most infections have a short incubation time, but symptoms can occur 60 days after a specific exposure.[24] The initial symptom typically is pain at the wound site. Infection can be limited to the wound, or it can disseminate rapidly, causing overwhelming septicemia with a high mortality rate.[20,87,88] Rapid progression to sepsis with metastatic abscesses to liver, lung, and spleen is striking.[24] Fever, nausea, vomiting, abdominal pain, and diarrhea frequently are noted. Septic shock, pneumonia, osteomyelitis, lymphadenitis, diarrhea, urinary tract infection, conjunctivitis, orbital cellulitis, and abscesses of spleen, lung, brain, and liver have been described.[20,89–95]

Pneumonia after aspiration of fresh warm water was reported in 2 cases of near drowning.[91] Multiple sites of abscesses tend to occur, especially in the liver, spleen, and lungs. Healthcare-associated infections and pneumonia have been reported.[96] Infections can recur.[88] Although most infections have occurred in people presumed to be immunologically competent, chronic granulomatous disease predisposes to *C. violaceum* infection.[95] One review suggested that patients with chronic granulomatous disease may have lower rates of bacteremia and death than patients without chronic granulomatous disease.[88] Similarities have been observed in clinical presentations of *C. violaceum* infection and the septicemic form of melioidosis caused by *Burkholderia pseudomalleii*.[89] Diagnosis is made by culture of wound exudate, biopsy specimen, blood, or abscess fluid.

Treatment and Prevention

Eikenella corrodens.

E. corrodens generally is susceptible in vitro to the following: penicillin, ampicillin, or amoxicillin; amoxicillin-clavulanate and ampicillin-sulbactam; most second- and third-generation cephalosporins; carbapenems; ureidopenicillins; tetracyclines; and newer fluoroquinolones.[34,97,98] Clindamycin, antistaphylococcal penicillins, macrolides, metronidazole, and aminoglycosides generally are inactive, and first-generation cephalosporins have variable activity. First-generation cephalosporins should not be given to patients with suspected *E. corrodens* infections.[35] β-Lactamase-producing strains have been reported rarely; these strains were highly susceptible to amoxicillin-clavulanate and ampicillin-sulbactam.[99] Because many infections involving *E. corrodens* are polymicrobial and can include anaerobic bacteria, selection of therapy should take into account other potential pathogens. Parenteral therapy is appropriate for initial therapy of severe infection, whereas amoxicillin or amoxicillin-clavulanate administered orally can be used to complete treatment in most instances. Surgical drainage of abscesses can be required. Standardized methods for in vitro antimicrobial susceptibility testing have been published.[100]

Pasteurella multocida.

P. multocida is susceptible to penicillin, which is the drug of choice for treatment of infections. Other active agents include ampicillin, amoxicillin-clavulanate, cefuroxime, cefoxitin, fluoroquinolones, tetracyclines, and trimethoprim-sulfamethoxazole.[97,101] Erythromycin, clindamycin, cephalexin, cefadroxil, cefaclor, and dicloxacillin have poor activity against *P. multocida* and should not be used to treat infection.[57,101,102] β-Lactamase–producing strains of *P. multocida* have been isolated from human infections.[69] One report noted that the addition of any of the β-lactamase–inhibiting compounds reduced the minimal inhibitory concentration of this organism at least 64-fold.[102] Testing for β-lactamase using a chromogenic cephalosporin (nitrocefin test) is recommended for isolates from normally sterile body sites. Standardized methods for in vitro testing of *Pasteurella* spp. have been published.[100,103]

Although most wound infections caused by *P. multocida* typically respond well to appropriate oral antibiotic therapy, worsening of disease during the first 24 hours of treatment is not unusual. When polymicrobial wound infection is suspected, amoxicillin-clavulanate or cefuroxime is recommended. The duration of oral antibiotic therapy for localized infections typically is 7 to 10 days.

Hospitalization should be considered for patients with certain *P. multocida* infections: systemic infections; infections in people with diabetes mellitus or immunocompromising conditions; and serious infections of the head, hands, joint spaces, or tendons. Parenteral antimicrobial agents active against *Pasteurella* spp. include penicillin, ampicillin, ampicillin-sulbactam, piperacillin, cefuroxime, and cefotaxime.[57,101] The duration of parenteral therapy for severe or disseminated infections should be 10 to 14 days. When mixed infection is considered, ticarcillin-clavulanate, cefuroxime, ampicillin-sulbactam, or meropenem should be effective.

Parents should be discouraged from allowing pets to lick infants and children on the face or on wounds. Handwashing after pet contact is prudent. Limiting contact with wild and domestic animals probably is the only way to prevent human infections with *Pasteurella* spp. Animal bites and scratches should be vigorously cleaned, irrigated, and debrided promptly. The use of antibiotic prophylaxis to prevent wound infection secondary to animal bites is controversial. Some experts recommend prophylactic antibiotic therapy in persons with the following: (1) cat bite; (2) severe bite wound accompanied by edema, crush injury, or involvement of bone, joint, or tendon sheath; (3) immunocompromising condition, asplenia, or diabetes mellitus; (4) injury sustained ≥8 hours before medical assistance is sought; and (5) bite on the hands, feet, or genital area.[57] Amoxicillin-clavulanate is a good choice when antimicrobial prophylaxis or preemptive therapy of a bite wound is indicated. For the penicillin-allergic child, trimethoprim–sulfamethoxazole or cefuroxime axetil can be considered. Minimal data exist about the role of suturing bite wounds and risk of infection.[57]

Chromobacterium violaceum.

C. violaceum usually is susceptible to chloramphenicol, aminoglycosides, tetracyclines, meropenem, fluoroquinolones, and trimethoprim-sulfamethoxazole but is resistant to penicillin, ampicillin, and first-generation cephalosporins.[20,21,89] Initial empiric therapy based on penicillins and cephalosporins can result in increased mortality rates.[63] Trimethoprim-sulfamethoxazole in combination with ciprofloxacin is the treatment of choice for initial therapy, but chloramphenicol in combination with an aminoglycoside, or a carbapenem, can be an effective alternate therapy.[98] Erythromycin is not effective for treatment, regardless of susceptibility test results, and resistance to the aminoglycosides and broad-spectrum β-lactam agents has been documented.[91,103] Antimicrobial susceptibility testing can be helpful in guiding management; however, currently no standardized methods exist for in vitro testing of *C. violaceum,* and test results should be interpreted cautiously. Antimicrobial therapy for infections with *C. violaceum* should be initiated with parenteral antibiotics until the patient is stable and improving, followed by oral therapy (trimethoprim-sulfamethoxazole, tetracycline, or a fluoroquinolone) for at least an additional 2 to 3 months, to prevent relapse.[24] Necrotizing skin lesions should be debrided and abscesses drained aggressively at initiation of antimicrobial therapy. Disseminated infection requires aggressive supportive care. Relapse of BSI is a documented complication, usually occurring approximately 2 weeks after completion of therapy. *C. violaceum,* along with the more common *Aeromonas hydrophila,* should be considered when choosing empiric antibiotic therapy for cellulitis or rapidly progressive illness following exposure to soil or water, particularly stagnant water in the southeastern United States.[20]

Key Points

Diagnosis and Management of *Eikenella corrodens* Infections

Microbiology

- Catalase-negative, oxidase-positive, small gram-negative, straight bacilli
- Good growth on blood and chocolate agars but not MacConkey agar; enhanced growth in carbon dioxide
- Colonies often showing a fringe of spreading growth and ability to pit the agar
- Generally susceptible to penicillin, but β-lactamase-producing strains reported (susceptible to penicillin or β-lactamase inhibitor compounds)

Epidemiology

- Normal oropharyngeal and transient gastrointestinal tract flora
- Associated with juvenile and adult periodontitis
- Oral, pleuropneumonic, and abdominal infections; often polymicrobial
- Wound infection associated with human bites and fist-to-mouth injuries
- Can cause bone and joint infection
- Agent of subacute bacterial endocarditis, especially subsequent to dental manipulation or intravenous drug abuse

Diagnosis

- Recovery in culture uses standard laboratory procedures.
- Polymerase chain reaction and 16S ribosomal RNA gene sequencing have been used for diagnosis but are not available widely.
- *Eikenella corrodens*–specific DNA probes have been used to analyze the microbial flora associated with periodontal disease.

Treatment

- Penicillin the drug of choice for infection because the organism is β-lactamase negative
- Susceptible generally to ampicillin and amoxicillin (if β-lactamase negative), amoxicillin-clavulanate, extended-spectrum cephalosporins, ciprofloxacin, and doxycycline; generally resistant to clindamycin and the macrolides

Duration of Therapy

- Response to therapy usually is rapid.
- Duration of therapy for systemic infection including osteoarticular infections or endocarditis is similar to that for other infectious agents.

Key Points

Diagnosis and Management of *Pasteurella multocida* Infections

Microbiology

- Catalase- and oxidase-positive, small gram-negative, coccoid to short bacilli
- Good growth on blood and chocolate agar but not MacConkey agar; does not require carbon dioxide

- Colonies can be mucoid, particularly those recovered from the respiratory tract.

- Generally susceptible to penicillin, but β-lactamase-positive strains causing penicillin and ampicillin resistance reported (susceptible to penicillin or β-lactamase inhibitor compounds)

Epidemiology

- Normal inhabitants of the nasopharynx, gingival, and oral cavity of a wide variety of wild and domestic mammals including cats and dogs; also found in the respiratory tract of birds

- Associated with wound infections following animal bites, scratches, or other exposures (licking of open skin lesions)

- Infected cat bites more likely than infected dog bites to contain *Pasteurella multocida*

- Causes respiratory tract infection including sinusitis and bronchitis, pneumonia, and empyema, primarily in people with underlying disease

- Two subspecies, *P. multocida* subsp. *multocida* and *P. multocida* subsp. *Septica,* the former responsible for the majority of infections

- Can cause bloodstream and disseminated infection, including meningitis, endocarditis, peritonitis, and bone and joint infection

Diagnosis

- Recovery in culture from most body sites uses standard laboratory procedures.

- Polymerase chain reaction and 16S ribosomal RNA gene sequencing have been used for diagnosis but are not available widely.

Treatment

- Penicillin the drug of choice for β-lactamase-negative infections
- Susceptible generally to ampicillin and amoxicillin (if β-lactamase negative), amoxicillin-clavulanate, extended-spectrum cephalosporins, ciprofloxacin, and trimethoprim-sulfamethoxazole; generally resistant to clindamycin, whereas macrolides and aminoglycosides have reduced activity

Duration of Therapy

- Response to therapy usually is rapid, particularly with administration of antibiotic parenterally; however, disease can progress initially after commencing an appropriate antibiotic, particularly an oral agent.
- Duration of therapy for systemic infection including osteoarticular infections or endocarditis is similar to that for other infectious agents.

Moraxella Species

Eugene Leibovitz, David Greenberg

Microbiology

Discovered at the end of the 19th century, *Moraxella catarrhalis* (formerly *Micrococcus catarrhalis*, *Neisseria catarrhalis,* and *Branhamella catarrhalis*) has undergone several changes of nomenclature and changes in status as either a commensal of the upper respiratory tract or a true pathogenic organism of both the upper and lower respiratory tract.[1–4] The morphologic and phenotypical similarity to *Neisseria* spp. led to the previous misidentification of *M. catarrhalis* as a species of *Neisseria, N. cinerea* (a commensal of the adult pharynx).[3,4] DNA-DNA and ribosomal RNA (rRNA)–DNA hybridization techniques have shown *M. catarrhalis* to be more closely related to *Moraxella* than to *Branhamella* spp.[3–7]

Currently, *M. catarrhalis* is responsible for up to 20% of cases of acute otitis media (AOM), (the third most common etiologic agent after nontypable *Haemophilus influenzae* and *Streptococcus pneumoniae*).[8–13] *M. catarrhalis* is the second (after *H. influenzae*) most common cause of exacerbations of chronic obstructive pulmonary disease in adults and is responsible for 2 to 4 million episodes in the United States.[14]

Members of the genus *Moraxella* are nonmotile, oxidase-positive, catalase-positive, aerobic, asaccharolytic, gram-negative coccobacilli or diplococci that tend to resist decolorization on Gram stain.[1] *M. catarrhalis, M. osloensis, M. nonliquefaciens,* and *M. lincolnii* are part of the normal flora of the respiratory tract, whereas *M. canis* is recovered from the upper respiratory tract of cats and dogs. Other pathogens include *Psychrobacter phenylpyruvicus;* the differentiation of *P. phenylpyruvicus* from *Brucella* spp. is important and requires microscopy and fermentation tests. Most laboratories do not perform species identification except for *M. catarrhalis*. Colonies of *M. catarrhalis* grow well on both blood and chocolate agar, and some strains also grow well on modified Thayer-Martin and other selective media. Colonies are grey white, opaque, and smooth. A useful observation for *M. catarrhalis* is the ability to push colonies over the surface of blood agar similar to a hockey puck on ice.[1] *M. catarrhalis* is distinguished easily from *Neisseria* spp. by the former's ability to hydrolyze ester-linked butyrate groups. Almost all contemporary *M. catarrhalis* isolates produce β-lactamase.[15,16]

M. catarrhalis colonizes the mucosal surfaces of the upper and lower respiratory tract by expression of adhesins and activation of metabolic pathways to overcome specific nutrient limitations. Several adhesins and receptors have been identified and characterized.[17] The family of ubiquitous surface proteins (Usps), consisting of at least 3 proteins (UspA1, UspA2, and UspA2H), consists of highly conserved and extensively studied outer membrane proteins (OMPs) with major roles in adhesion, invasion, and resistance to classic and alternative complement systems. The whole genomic sequence of *Moraxella catarrhalis* strain RH4 (16S rRNA subtype 1strain) has been reported.[18] The *Moraxella* immunoglobulin D (IgD)–binding protein (MID, also named hemagglutinin) is another extensively studied and highly conserved OMP that has a unique ability to bind IgD and also type II alveolar epithelial cells.[17,19] Fifty-seven proteins carried by outer membrane vesicles (OMVs) have been identified, including UspA1, UspA2, MID, lipo-oligosaccharide, and DNA.[20] UspAs are the most important complement-resisting OMPs, as demonstrated in clinical isolates from patients with otitis media or chronic obstructive pulmonary disease.[17,20–22] Strains resistant to complement-mediated killing are more virulent and adherent to epithelial cells.[17,23,24] The membrane lipo-oligosaccharides also are considered important for *M. catarrhalis* adhesion and virulence.[17,25]

M. catarrhalis can form biofilms in vitro and has been detected in biofilms in the middle ear of patients with chronic otitis media.[26–28] Biofilm production by *S. pneumoniae* and *M. catarrhalis* is proposed to enhance the roles of these pathogens in recurrent AOM and otitis media with effusion.[29]

At the respiratory tract mucosal level, *M. catarrhalis* activates an proinflammatory response that is mainly dependent on toll-like receptor 2 (TLR2),[17,30] and it also can inhibit the inflammatory cascade, thereby leading to evasion and persistent mucosal surface colonization.[31]

The importance of *M. catarrhalis* in the post–pneumococcal conjugate vaccine 13 (PCV13) era and its increasing resistance to antimicrobial agents foster consideration of a vaccine for *M. catarrhalis*.[16,17,32,33] UspA1, UspA2, and MID/hemagglutinin are considered important OMP adhesin candidates for development of a vaccine.[34,35] The chinchilla model has promise as a relevant animal model for human vaccine development.[36,37]

Epidemiology

Colonization rates with *M. catarrhalis* in the upper respiratory tract vary with age, with rates highest in the first year of life (28% −100%).[38,39] *M. catarrhalis* can persist for several months, and earlier colonization in the first year is associated with higher risks of AOM and recurrent disease.[39] Seasonal peaks of *M. catarrhalis* colonization and disease (winter and spring) are similar to several viral respiratory viruses.[40,41] In the chinchilla, coinfection of respiratory syncytial virus and *M. catarrhalis* facilitated ascension of *M. catarrhalis* from the nasopharynx into the middle ear.[42] Physiologic cold shock[43,44] of *M. catarrhalis* is associated with expression of important virulence factors, such as genes involved in adherence to epithelial cells, iron acquisition, serum resistance and immune evasion.[44] The risk of repeated *M. catarrhalis* colonization was reported to be increased in children with TLR4 Asp299Gly polymorphism.[45] Conversely, the pili (fimbriae), cell surface organelles found on the surface of *M. catarrhalis,* enhance pathogen clearance from the middle ear, probably mediated through neutrophil-dependent TLR5 signaling.[46]

Five percent to 32% of older adults with chronic obstructive pulmonary disease may have, at any time, *M. catarrhalis* colonizing the respiratory tract, with a median carriage duration of 30 to 40 days.[47]

The development of mature specific IgG antibodies against *M. catarrhalis* is slow, and children <4 years of age have low titers of IgG antibodies.[48] In a study analyzing the humoral immune responses to potential *M. catarrhalis* vaccine candidates from birth to 2 years of age, the level of antigen-specific IgG was lower than that obtained from umbilical cord blood.[49]

The most frequent infections caused by *M. catarrhalis* are AOM, sinusitis, bronchitis, and pneumonia. Most cases of *M. catarrhalis* AOM resolve spontaneously. Compared with AOM caused by other pathogens, *M. catarrhalis* AOM is more often a mixed-infection AOM, and it is less often associated with spontaneous perforation and mastoiditis.[50] *M. catarrhalis* hardly ever causes suppurative complications of AOM, such as osteomyelitis, meningitis, or brain abscess. Although major decreases in pneumococcal AOM, with near elimination of PCV13 serotype disease in the post-PCV13 era, are well documented,[51] the dynamics of *M. catarrhalis* AOM are unknown. No change in the nasopharyngeal carriage of *M. catarrhalis* was observed in children <2 years of age following PCV7.[52]

Establishing a causative role for *M. catarrhalis* in children with community-acquired pneumonia is challenging because of poor diagnostic tests and frequent colonization of the upper respiratory tract.[53,54] *M. catarrhalis* bacteremia is infrequently reported; it occurs in children <2 years of age, usually in association with community-acquired pneumonia, and is characterized by low grade fever and a lack of leukocytosis but prolonged hospitalizations.[55]

M. catarrhalis can cause purulent conjunctivitis, periorbital cellulitis, endophthalmitis, pyogenic arthritis, pancreatitis, pericarditis, endocarditis, prosthetic vascular graft infections, pleural effusion, or localized abscesses.[56–66] In immunocompromised patients, *M. catarrhalis* septicemia is reported in patients with leukemia, acquired immunodeficiency syndrome, and agammaglobulinemia.[67–69]

Septicemia associated with diarrhea in children that is caused by *M. osloensis, M. nonliquefaciens,* and *M. lacunata* has been reported.[70] Septicemia, endocarditis, and pyogenic arthritis caused by *M. liquefaciens* and *M. nonliquefaciens* has also been reported.[70–74] *M. osloensis* has been associated with osteomyelitis, peritonitis, catheter-related bloodstream infection, and other deep-seated infections.[75] *M. canis,* an inhabitant of the upper respiratory tract of dogs and cats, has been associated with rare cases of bloodstream infection, wound infections following dog bites, and ulcerated metastatic lymph node infection.[76,77]

Treatment

Most *Moraxella* spp. other than *M. catarrhalis* are susceptible to penicillin and ampicillin, cephalosporins, tetracyclines, macrolides, aminoglycosides, and quinolones; however, β-lactamase–producing strains have been identified in some species, including strains of *M. osloensis* and *P. phenylpyruvicus.*[1,78,79] The prudent approach is to test clinically significant isolates for β-lactamase production. All 117 *M. catarrhalis* isolates tested during 2012 in British Columbia were sensitive to amoxicillin-clavulanate, doxycycline, clarithromycin, levofloxacin, and trimethoprim-sulfamethoxazole, and only 1 isolate was intermediately resistant to cefuroxime.[80]

M. catarrhalis is almost uniformly resistant to penicillin, ampicillin, and amoxicillin because of the production of a *Branhamella/Moraxella* (BRO)-1 or BRO-2 β-lactamase.[1,81,82] The drug of choice to treat *M. catarrhalis* infections is amoxicillin-clavulanate. Second- or third-generation cephalosporin drugs are alternative therapeutic agents. With a wide variety of antimicrobial agents (including fluoroquinolones and carbapenems) uniformly active against *M. catarrhalis*, the need rarely exists for susceptibility testing except for β-lactamase, which also aids identification.[1,82] Strains of *M. catarrhalis* with low-level fluoroquinolone resistance and resistance to both macrolides and quinolones have been reported.[83,84]

Pseudomonas Species and Related Organisms

Jane L. Burns

Pseudomonas spp. are water and soil organisms of relatively low virulence that are catalase-producing, nonglucose-fermenting, gram-negative bacilli that grow well on routine microbiologic culture media at 37°C. Pseudomonads are motile and both indophenol and oxidase positive; many produce pyoverdins or other visible or fluorescent pigments. Speciation is based primarily on physical characteristics (pigment production, odor, colonial morphology, and flagellar structure) and biochemical profiles (including carbohydrate fermentation patterns and production of arginine dihydrolase and lysine decarboxylase). Several related genera are recognized, many of which used to be species within the genus *Pseudomonas* (Box 154.1). Still remaining within the genus are *P. aeruginosa, P. stutzeri, P. putida,* and *P. fluorescens. P. oryzihabitans* (formerly *Flavimonas*) and *P. luteola* (formerly *Chryseomonas*) have been returned to the genus (Table 154.1).[1,2]

Box 154.1

Closely Related Genera Formerly Included With *Pseudomonas*

Acidovorax

Brevundimonas

Burkholderia

Comamonas

Delftia

Methylobacterium

Ralstonia

Shewanella

Sphingomonas

Stenotrophomonas

TABLE 154.1

Human Pathogens Included Within the Genus *Pseudomonas* (Non-*aeruginosa*)

Species	Subspecies
Pseudomonas fluorescens species complex	23 species
Pseudomonas luteola	(Formerly *Chryseomonas luteola*)
Pseudomonas monteilii	(Closely related to *Pseudomonas putida*)
Pseudomonas oryzihabitans	(Formerly *Flavimonas oryzihabitans*)
Pseudomonas putida	2 biovars
Pseudomonas stutzeri	18 genomovars

Pseudomonads and closely related species are nutritionally diverse; many are used in industry because of their unique ability to catabolize toxins. Although *P. aeruginosa* is the most important human pathogen within this group, other species have been reported to cause nosocomial infections in immunocompromised and postoperative patients and in patients with indwelling catheters and to cause sporadic infections in previously healthy people. In addition, some organisms occupy specific environmental niches. Several species, including *P. fluorescens* and *Ralstonia* spp., are isolated commonly from the sputum of patients with cystic fibrosis but are of unknown clinical significance. *R. mannitolilytica* is the most commonly isolated *Ralstonia* species from patients with cystic fibrosis (46% of *Ralstonia*-positive patients), followed by *R.*

respiraculi and *R. pickettii* (19% and 18%, respectively).[3] Other pediatric isolates of *Ralstonia* occur mainly in patients with nosocomial infections and among patients with infections and malignant disease.[4] In 2011, *R. paucula* was reported in an outbreak of pseudobacteremia within a pediatric emergency department that was associated with a skin antiseptic.[5] *Sphingomonas paucimobilis* can cause nosocomial infections, most commonly in immunocompromised people; contaminated solutions often are the cause.[6] Bloodstream infection in the presence of a central venous catheter has been reported in children with neonatal sepsis, malignant disease, and aplastic anemia; patients undergoing continuous peritoneal dialysis also are at risk for catheter-associated peritonitis.[7]

The fluorescent group of *Pseudomonas* includes *P. aeruginosa, P. fluorescens, P. putida, P. veronii*, and *P. monteilii*. DNA sequence analysis has resulted in reclassification of strains previously identified as *P. fluorescens* into the *P. fluorescens* species complex (23 species, including *P. fluorescens* and *P. veronii*).[8] These organisms have been described in both nosocomial and community-associated infections in children, including bloodstream infection, pneumonia, urinary tract infection, and postoperative wound infection.[9] In 2008, a multistate outbreak of *P. fluorescens* bloodstream infection was reported, associated with exposure to contaminated heparinized saline flushes.[10] A case series from 2007 reported an outbreak of *P. aeruginosa* and *P. putida* catheter-associated infections associated with contaminated tap water on a pediatric oncology unit.[11] Because these organisms are uncommon human pathogens, few studies of susceptibility of these organisms have been conducted; in vitro susceptibility testing should guide therapy.

P. oryzihabitans, P. luteola, and *P. stutzeri* are members of the nonfluorescent group. Although they are rare human pathogens, these organisms are reported occasionally as nosocomial pathogens in both previously healthy and immunocompromised people. *P. oryzihabitans* has been described as an etiologic agent of bloodstream infection in premature neonates and in children with malignant disease, postoperative infections, and catheter-associated infections.[12,13] Case reports of *P. luteola* causing brain abscess, meningitis, and endocarditis and a case series of 7 pediatric patients with bacteremia have been published.[14–16] *P. stutzeri* has been reported to cause posttraumatic pyogenic arthritis and postoperative brain abscess.[17,18] Other pseudomonads, including *Brevundimonas vesicularis, Delftia acidovorans, Comamonas testosteroni, Acidovorax avenae,* and *Shewanella putrefaciens,* can cause sporadic infections or nosocomial outbreaks in immunocompromised people but have not been identified as significant human pathogens.[19–23]

Pseudomonas aeruginosa

Paul J. Planet

Microbiology

Pseudomonas aeruginosa is a gram-negative bacillus found widely in nature, in soil and water. Classified as an opportunistic pathogen, *P. aeruginosa* causes disease infrequently in normal hosts but is a major cause of infection in patients with underlying or immunocompromising conditions. The genome of *P. aeruginosa*, which is especially large for a prokaryote, has provided an understanding of the metabolic and pathogenic mechanisms that underlie the success of this versatile pathogen, and it has become a model for understanding microbial genomic variation and evolution in chronic disease. *P. aeruginosa* has few nutritional requirements and can adapt to conditions not tolerated by other organisms. It does not ferment lactose or other carbohydrates but oxidizes glucose and xylose. Organisms grow aerobically or anaerobically if nitrate is available as an inorganic electron acceptor, as is the case in the lungs of patients with cystic fibrosis (CF).[1] *P. aeruginosa* gene expression responds to environmental conditions with discrete patterns typical of environmental isolates: motility, piliation, and expression of numerous exoproducts. In subacute and chronic infections, the accumulation of intracellular dinucleotides (cyclic diguanidine monophosphate) favors a biofilm mode of growth with the formation of an extracellular polysaccharide matrix,[2] thus enabling the organisms to avoid innate immune clearance mechanisms and persist in human airways.[3]

The organism produces the fluorescent siderophores pyoverdin and pyochelin, which function to scavenge iron. Redox-active phenazines such as pyocyanin, the pigment that gives *P. aeruginosa* its characteristic blue color, play an important role in electron transport especially under microaerophilic conditions, increase the bioavailability of iron, and enhance virulence through oxidative stress.[4,5] *P. aeruginosa* can be identified biochemically as having indophenol oxidase-positive, citrate-positive, and L-arginine dehydrolase-positive activity. Differentiation of *P. aeruginosa* from other pseudomonads or organisms such as *Burkholderia* species, *Stenotrophomonas maltophilia,* and *Achromobacter* spp. occasionally can require testing for DNAse activity, growth at 42°C, and differential carbohydrate metabolism or using molecular methods.

Virulence Factors and Pathogenesis

Multiple virulence factors and their purported roles in pathogenesis are shown in Table 155.1. *P. aeruginosa* thrives under conditions that would be adverse to many other bacteria with only a minimal carbon source and a moist environment. *P. aeruginosa* is intrinsically resistant to many classes of antimicrobial agents and can acquire additional resistance genes from other organisms, thus flourishing under selective pressures that eliminate competing flora. Depending on specific environmental conditions (e.g., availability of nutrients, especially iron) and immune responses, specific virulence factors are expressed in a highly regulated manner. Hosts without underlying conditions occasionally experience serious *P. aeruginosa* infections if a break in normal barrier defenses occurs through puncture wounds,[6] skin trauma, or burns.[7] More commonly, *P. aeruginosa* acts as an opportunist, infecting patients who have defective mucosal immunity, impaired pulmonary clearance as in CF, or disease-induced or iatrogenic neutropenia.[8,9]

TABLE 155.1

Virulence Factors of *Pseudomonas aeruginosa*

Component	Mechanism	Role in Pathogenesis

Type IV pilus	Adhesin: recognizes the GaINAcbeta1-4Gal receptor in asialoglycolipids	Mediates attachment to epithelial surfaces, provides twitching motility essential for biofilm formation, activates inflammation
Flagella	Motility, chemotaxis, mucin-binding, major immunostimulant through toll-like receptor 5 recognition	Facilitates tissue invasion, activates inflammation
Alginate mucoexopolysaccharide	Antiphagocytic	Characterizes chronic infections in cystic fibrosis
Elastase	Cleaves elastin, proteins including IgA	Destroys extracellular matrix components
Alkaline protease	Cleaves proteins	Causes tissue destruction
Phospholipase C (hemolytic and nonhemolytic)	Cleaves phosphatidylcholine and sphingomyelin	Degrades pulmonary surfactant, facilitates infection in the lung
Phospholipase D (PldA and PldB; type VI secretion)	Activates PI3K/Akt pathway	Facilitates intracellular invasion through actin rearrangement
Neuraminidase	Releases sialic acid from glycoconjugates	Facilitates colonization
Cytotoxin	Forms pores in membranes	Causes tissue destruction
Pseudomonas **autoinducer (PAI)**	Homoserine lactone derivative, a secreted cofactor necessary for the expression of elastase, alkaline protease, neuraminidase, and biofilm formation	Coordinates gene expression within a population of organisms
Exotoxin A	ADP ribosylating enzyme, which inactivates EF-2, inhibiting protein synthesis	Causes tissue destruction
Exoenzyme S, T, U (type III secreted toxins)	ADP ribosylating enzymes (S and T) and toxins with specific eukaryotic targets, including GTPases; phospholipase A_2	Facilitates invasion, cytotoxicity, interferes with cytoskeletal integrity
Siderophores (pyochelin, pyoverdin)	High-affinity iron-binding capacity	Facilitates iron acquisition for bacterial metabolism
Phenazines (pyocyanin)	Blue-green pigment: oxidant activity	Destroys ciliary activity, toxic to airway cells, oxidative stress

ADP, adenosine diphosphate; EF-2, elongation factor-2; GTPases, guanosine triphosphatases; IgA, immunoglobulin A.

P. aeruginosa expresses numerous virulence factors that stimulate both airway epithelial cells and professional immune cells to produce proinflammatory cytokines and chemokines, such as interleukin-8 (IL-8),[10] IL-17A/F,[11] granulocyte-macrophage colony-stimulating factor,[12] and mucin.[13] Secreted exoenzymes interact with specific eukaryotic targets to affect cytoskeletal components and thereby disrupt the integrity of the epithelial tight junctions and induce inflammation.[13] Products of type III secretion systems (T3SS) are expressed commonly in acute infection, often in the setting of hospital-acquired pneumonia, by causing cytotoxicity and facilitating invasion.[14] The T3SS effector proteins include exoenzyme U (ExoU), a potent phospholipase A_2 that requires host superoxide dismutase for activation and often is associated with severe pneumonia[15]; ExoS or ExoT, closely related toxins with both adenosine diphosphate (ADP) ribosyltransferase activity and Rho GTPase activating protein activity,[14] are expressed commonly in clinical isolates from acute infections. The T3SS virulence factors have been associated with severe *P. aeruginosa* pneumonia in hospitalized patients,[16] and they have been targeted as potential antigens in *Pseudomonas* vaccines and immunotherapy.

The more recently discovered type VI secretion systems (T6SS) export toxins for interbacterial competition, but the secreted effectors also enhance invasion of host cells through activation of the PI3K/Akt pathway to cause actin rearrangement.[17] Other bacterial products such as phenazines (e.g., pyocyanin), initially considered to be metabolic waste products, have strong effects on other microorganisms and also are toxic to host cells through oxidative stress.[18]

Whereas lipopolysaccharide often is considered to be the major immunostimulatory factor in gram-negative bacteria, *P. aeruginosa* lipopolysaccharide does not activate proinflammatory signaling as potently as does lipopolysaccharide of other organisms.[19] *P. aeruginosa* flagella are important in pathogenesis signaling through toll-like receptor 5 (TLR5) and the inflammasome leading to proinflammatory responses to the organisms.[20–22] Indeed, the inflammasome plays a central role in the immune response to *P. aeruginosa* by being activated by bacterial products including flagellins,[21,22] type IV pilins,[23] T3SS components,[22,24] and the toxin RhsT.[25] Inflammasome activation also appears to be dampened by several of the T3SS effectors.[26,27] Whether the inflammasome response to *P. aeruginosa* is beneficial or detrimental to the host, either by aiding to clear bacterial infection or by causing increased tissue destruction, is likely to depend on the specific clinical circumstances.

During infection of patients with CF, shedding of bacterial immunostimulants activates cytokine and chemokine production by airway epithelial cells and recruited immune cells. After the initial steps of colonization, *P. aeruginosa* undergoes gene regulatory changes that aid in the establishment of persistent infection. The milieu within the CF-affected airways is relatively anaerobic, a property that affects both bacterial gene expression and antimicrobial susceptibility.[28] Once a sufficient density of organisms is resident in the airways, bacterial gene expression is regulated by a quorum sensing system, which involves the secretion of freely diffusible homoserine lactones that act along with transcriptional activators to coordinate the gene expression of the entire population of bacteria. Quorum sensing facilitates a biofilm mode of growth, by turning off expression of the more immunostimulatory gene products such as exoenzymes and flagella while favoring secretion of exopolysaccharides.[29] Although few organisms are directly adherent to the epithelial surface, high density of organisms persists in biofilm-like aggregates in the airways as a result of reduced mucociliary clearance and loss of airway surface hydration.[30] Because organisms within biofilms are relatively less susceptible to antimicrobial agents and phagocytosis, the ability to persist in biofilms provides a major selective advantage to the species.[31]

In chronic CF infections, *P. aeruginosa* strains tend to accumulate genetic changes that diminish or eliminate expression of proinflammatory bacterial products such as flagella or pili with the appearance of *muc* mutants with copious production of the extracellular alginate,[32] a phenotype that is virtually pathognomonic for CF isolates.[33] Although resistant to phagocytosis, these organisms are not invasive, but they chronically infect the airways. Together these changes have a profound impact on host inflammation.[34] Longterm infections also lead to high levels of phenotypic and genomic diversity that likely have an impact on the overall fitness of the infecting bacterial population.[35] This reproducible evolutionary tendency has been studied in detail using whole genomes,[36,37] and it may be enhanced by higher rates of mutation in these strains.[38] The tendency to adapt in specific ways suggests that chronic inflammation may not be beneficial for the bacterium.

Epidemiology and Clinical Manifestations

P. aeruginosa is associated with a wide variety of infections, depending on the nature of the host and the severity of underlying disease, ranging from self-limited folliculitis[39] to overwhelming septic shock.[40] Because of its exceptional genetic plasticity, *P. aeruginosa* adapts readily to healthcare settings and is a major cause of healthcare-associated infections,[41] including ventilator-associated pneumonia and infections of indwelling catheters.[42] Genomic sequencing studies suggest that a relatively limited number of clones may be responsible for these infections, but with extensive phenotypic diversity within clones.[43] Patients with CF generally have a phase of intermittent colonization with a variety of distinct *P. aeruginosa* strains, followed by chronic infection with single clones with adapted virulence profiles.[44] Although most strains appear to be acquired from the environment,[45] several transmissible strains (e.g., Liverpool Epidemic Strain) have been identified.[46,47] Tables 155.2 and 155.3 show the epidemiology and clinical manifestations of *P. aeruginosa* infection in normal and special hosts, respectively.

TABLE 155.2

Epidemiology and Clinical Manifestations of Community-Acquired and Nosocomial *Pseudomonas aeruginosa* Infection in the Normal Host

Infection	Clinical Characteristics
COMMUNITY-ACQUIRED	
Ocular infection	Keratitis is common after minor eye trauma (as in wearers of contact lenses) or penetrating eye trauma; treatment often involves subtenon or intravitreal injections
Otitis externa	“Swimmer's ear” is associated with excessive moisture, or otitis externa results from chronic suppurative otitis media; topical treatment is sufficient; malignant otitis externa is a severe systemic infection usually limited to diabetic patients and other compromised hosts; parenteral therapy and debridement are required
Endocarditis	Intravenous drug abusers can develop *Pseudomonas aeruginosa* endocarditis,

	usually of the tricuspid valve; injected foreign materials can damage endothelium and create a niche for injected organisms to adhere; septic emboli cause pneumonia; therapy can require surgical intervention
Bone and soft tissue infection	Puncture wounds of the foot are complicated especially by *P. aeruginosa* infection because the organisms are found in the moist environment within the soles of sneakers; biopsy of bone can be necessary to differentiate osteomyelitis from a contaminated drainage tract, and exploration can be necessary to remove a retained foreign object
Folliculitis	Immersion in contaminated bathtubs, hot tubs, and pools has been associated with superficial, self-limited infection, commonly confined to abraded areas and those areas covered by bathing suits; infants or patients who experience cellulitis can have severe systemic signs of infection and require anti-*Pseudomonas* treatments
NOSOCOMIAL	
Respiratory tract infection	Ventilator-associated pneumonia, intubation, and use of broad-spectrum antibiotics predispose to pneumonia; *P. aeruginosa* pneumonia (fever, purulent secretions, necrotizing pneumonia, and respiratory deterioration) must be differentiated from colonization; outbreaks of *P. aeruginosa* respiratory infection in intensive care units suggest contamination of a common source (e.g., respiratory equipment, sinks, blood pressure transducers, or common intravenous flush vials)
Urinary tract infection	Use of prophylactic or broad-spectrum antibiotics, indwelling urinary catheters, another foreign body, and obstruction are predisposing factors; successful treatment almost always requires removal of the foreign body
Surgical infection	Wound infection can follow neurosurgical, urologic surgical, or orthopedic surgical procedures; osteomyelitis is an infrequent complication that often requires debridement to effect a cure; antimicrobial therapy is prolonged, with few clinical end points; neurosurgical infections involving shunts require removal of the foreign material

TABLE 155.3

Epidemiology and Clinical Manifestations of *Pseudomonas aeruginosa* Infections in Special Hosts

Infection	Clinical Characteristics
NEUTROPENIA OR NEUTROPHIL DYSFUNCTION	
Septicemia	This healthcare-associated infection and complication of chemotherapy causes profound neutropenia, associated with higher mortality and morbidity rates than infection with other pathogens; successful outcomes are associated with recovery or engraftment of bone marrow, recovery of neutrophils; it affects immunodeficient patients and extremely low birth weight infants
	Central venous access devices are a source
Ecthyma gangrenosum	These erythematous tender lesions with an area of central necrosis are usually manifestations of or are associated with septicemia; perianal lesions portend poor outcome (Figs. 155.1–155.3)
CNS infection	Infection occurs by direct extension from sinuses, bacteremic spread, or secondary to contamination of shunts or reservoirs; in immunosuppressed patients, CNS infections can be insidious
HIV INFECTION	
Pneumonia or bacteremia	*Pseudomonas aeruginosa* is a rare cause of community-acquired pneumonia in HIV-infected adults and children, usually those *not* receiving effective antiretroviral therapy
Burns	Burn wound sepsis is a complication accompanied by high mortality rates; meticulous debridement, grafting, and judicious use of antibiotics can help to

	decrease the incidence of most such infections
Cystic fibrosis	Infection usually occurs early in infancy and childhood and leads to neutrophil-dominated inflammation of the airway, chronic inflammation, fibrosis, and loss of pulmonary function; aggressive anti-*Pseudomonas* therapy and control of inflammatory response are mainstays of therapy

CNS, central nervous system; HIV, human immunodeficiency virus.

Antibiotic Resistance

Epidemiologic Trends

Intrinsic virulence factors and facile acquisition of antimicrobial resistance in response to immune and chemotherapeutic pressure make *P. aeruginosa* a formidable pathogen in healthcare settings. Numerous reports of human clinical isolates document resistance to all available antimicrobial agents including polymyxins.[48] Moreover, particularly in patients harboring large numbers of organisms, as in CF, hypermutable strains are recovered that have increased rates of spontaneous mutations resulting from alterations in the DNA mismatch repair systems.[49] Such hypermutable strains rapidly acquire resistance to multiple antimicrobial agents. National surveillance of antimicrobial resistance rates for *P. aeruginosa* suggests relatively stable resistance trends,[50] but with important geographic differences in resistance patterns across the United States.

Mechanisms of Antibiotic Resistance

Permeability Factors and Efflux Systems.

Analysis of the *P. aeruginosa* genome demonstrates that multiple redundant mechanisms survive potential threats from antimicrobial agents, a likely consequence of the origin of this organism in the soil commensurate with fungi that produce common antimicrobial agents. The organism's ability to limit permeability through several efflux pumps is paramount. These efflux pumps are important in export of quorum sensors (that regulate biofilm production), invasiveness, and antimicrobial resistance.[51] The *mexAB* operon likely accounts for “intrinsic” resistance of *P. aeruginosa* to many classes of antibiotics, including tetracyclines, fluoroquinolones, chloramphenicol, macrolides, and trimethoprim, as well as β-lactam agents and β-lactamase inhibitors. Genome analysis reveals at least

20 homologues of the mexAB system in *P. aeruginosa.* The combination of limited permeability (increased efflux) and strategically placed enzymes such as β-lactamases within the periplasmic space accounts for much of the antimicrobial resistance of the species.

β-Lactamase Production.

P. aeruginosa expresses both chromosomally mediated and plasmid-associated enzymes that degrade β-lactam antibiotics. Chromosomal expression of *ampC* induces an enzyme that preferentially cleaves the 6-membered nucleus of the cephalosporin family and is a conserved gene in this species. Although normally repressed, this chromosomally encoded enzyme can be induced, particularly by cephalosporin compounds. This enzyme is not inhibited by the β-lactamase inhibitors currently in clinical use, tazobactam and clavulanate.[52] In addition, *P. aeruginosa* proficiently accepts plasmid-mediated β-lactamases of many different types. These constitutively expressed enzymes readily cleave most penicillins. β-Lactamase enzymes with inhibition of extended-spectrum β-lactam agents are increasingly common and have significant activity against a variety of β-lactam and carbapenem structures. Whereas the most common TEM-type plasmid-mediated β-lactamases are susceptible to clavulanate and tazobactam, many more recently identified extended-spectrum β-lactam agents are resistant. Large numbers of bacteria, frequently associated with pulmonary infections such as in patients with CF or in burn wounds, facilitate the selection of mutants resistant to entire classes of antimicrobial agents.

Aminoglycoside-Modifying Enzymes.

Plasmid-encoded or transposon-associated enzymes that can acetylate, phosphorylate, or adenylate specific sites on aminoglycosides can be associated with clinically significant aminoglycoside resistance. The prevalence of these genes varies widely among healthcare facilities. In general, amikacin is less susceptible to modification by these enzymes than is tobramycin or gentamicin, and rates of resistance to amikacin are lower compared with other aminoglycosides. Most aminoglycoside resistance, however, stems from efflux systems resulting in limited uptake of the drug, either alone or in combination with these enzymes.

Treatment

Uncomplicated Infections in a Normal Host.

The major clinical considerations in treating *P. aeruginosa* infections involve the health of the host, immunocompetence, the site of infection, the size of the bacterial inoculum, and the potential for antimicrobial resistance. Thus, in a healthy adolescent with *P. aeruginosa* osteomyelitis associated with a puncture wound, or folliculitis acquired in a hot tub, a single drug with high activity against the isolate would be sufficient, and the patient could be treated orally. Similarly, otitis externa (swimmer's ear) in a healthy child, commonly caused by *P. aeruginosa,* often can be treated topically, whereas otitis externa in a patient with diabetes requires systemic and usually parenteral therapy. Systemic illness caused by *P. aeruginosa* usually is treated with 2 drugs likely to have synergistic activity against the organism. The outcome of *P. aeruginosa* bloodstream infection is improved significantly if the empiric regimen includes at least 1 antibiotic with activity against the *P. aeruginosa* organism isolated.[53] Surveys across the US indicate the following rates of *P. aeruginosa* susceptibility: piperacillin-tazobactam, 86%; ceftazidime, 80%; ciprofloxacin, 67%; and levofloxacin, 67%.[50] Isolates from patients with CF generally are more resistant than isolates from people without CF.

Infection in Immunocompromised Hosts.

Despite the lack of well-controlled, blinded studies, most clinicians would treat a “serious” *P. aeruginosa* infection (e,g., a bloodstream infection in a neutropenic host or sepsis in a premature infant) with 2 antipseudomonal agents likely to have synergistic activity. Because oncology patients and particularly patients who undergo stem cell transplantation often have prolonged periods of neutropenia and frequent febrile episodes, empiric antimicrobial regimens in such patients always include agents with activity against *P. aeruginosa.* Fluoroquinolones or β-lactam agents are commonly combined with an aminoglycoside despite the potential for renal toxicity (especially in this patient population). The frequency of *P. aeruginosa* infection in these patients has decreased substantially, whereas the isolation of gram-positive pathogens and fungi has increased. Most patients with CF are managed with longterm inhaled tobramycin and several other antimicrobial agents (e.g., aztreonam and amikacin), which also can be delivered by inhaled aerosol. Exacerbations in CF often are treated in the outpatient setting, and this treatment can include parenteral therapy.

Renal Infection.

Because extremely high concentrations of most of the antipseudomonal antibiotics are achieved in the urine of patients with normal renal function, most urinary tract infections can be treated with a single agent. In patients with urinary tract obstruction, renal stones, or foreign bodies, antimicrobial therapy alone often fails or a relapse of the infection occurs because the organisms commonly form biofilms in this setting and are substantially less susceptible to antimicrobial agents.

Central Nervous System Infections.

P. aeruginosa shunt infections generally are treated with removal of the contaminated shunt. Agents that cross the blood-brain barrier and have high anti-*P. aeruginosa* activity, such as the carbapenems[54] or fluoroquinolones,[55] usually are effective. Because aminoglycosides do not accumulate in the central nervous system, these drugs are of questionable value.

Ocular Infections.

Usually associated with accidental or surgical trauma, ocular infection requires urgent and careful ophthalmologic examination to define the extent of the infection and guide the aggressiveness of antipseudomonal therapy. Superficial infections may respond to topical therapy; superfortified aminoglycoside and fluoroquinolone preparations for ocular administration are available. More invasive infections require intraocular treatment to achieve high local levels of drug. Ciprofloxacin and imipenem have some ocular penetration.[56] Infection of the vitreous or anterior chamber usually requires intravitreal or subtenon administration of the antibiotic, chosen according to results of specific susceptibility tests, and vitrectomy can be required.

Pulmonary Infections.

Because pneumonia usually involves a high inoculum, treatment conventionally includes 2 antipseudomonal agents that are likely to be synergistic. This regimen usually includes a β-lactam agent such as piperacillin-tazobactam, a fluoroquinolone, or an aminoglycoside. Antipseudomonal cephalosporins (ceftazidime or cefepime) also are effective, although these drugs can select for mutants with constitutive expression of the *ampC* chromosomal enzyme. Carbapenems (imipenem, meropenem, and ertapenem) often are chosen when the isolate is resistant to other agents, particularly when it expresses extended-spectrum β-lactamase. In patients with CF who require parenteral therapy, an aminoglycoside (often inhaled tobramycin) is used with a β-lactam agent or a fluoroquinolone. Fluoroquinolones (ciprofloxacin and levofloxacin) are used widely, both as single agents and in combination with other classes of drugs. Aminoglycosides can be given in large doses by the aerosol route for these pulmonary infections without systemic side effects (see Chapter 106).

Single daily dosing of aminoglycosides is used frequently and appears effective on the basis of studies performed in neonates, children with CF, and neutropenic hosts.[57] The carbapenems and monobactam-aztreonam regimens generally are reserved for patients with infections caused by organisms resistant to the other β-lactam agents or for patients with renal disease who are at risk of aminoglycoside-related nephrotoxicity. Patients with multidrug-resistant isolates have been treated successfully with colistin (polymyxin),[58] as well as with polymyxins that can be delivered by aerosol.[59]

Prevention

Nosocomial acquisition of the organism is prevented through careful hand hygiene practices, prevention of exposure to high-density organisms from water sources, and adherence to general principles of infection control. Avoidance of uncooked foods, including raw fruits and vegetables, in neutropenic patients can decrease ingestion of *P. aeruginosa*. Despite decades of interest in the development of an antipseudomonal vaccine for patients known to be at high risk, no vaccine is currently available. A flagellin-based vaccine has been developed for use in patients with CF, but it has been difficult to evaluate because of the efficacy of routine prophylactic antimicrobial therapy for *P. aeruginosa.*[60]

Burkholderia cepacia Complex and Other *Burkholderia* Species

Jane L. Burns

The genus *Burkholderia* was proposed in 1992 for 7 species that previously were included in *Pseudomonas* homology group II.[1] All are animal or plant pathogens but are not significant pathogens in healthy humans. *Burkholderia* spp. are nutritionally diverse water and soil organisms that are catalase producing and nonglucose fermenting. Species are distinguished primarily on the basis of phenotype and biochemical characteristics (including carbohydrate fermentation patterns and production of indophenol oxidase).

Infections associated with *Burkholderia* spp. are shown in Table 156.1. *B. cepacia* complex has been associated with severe pulmonary infections in patients with cystic fibrosis (CF) and with fatal bloodstream infection (BSI) in patients with chronic granulomatous disease (CGD). *B. pseudomallei* is the cause of melioidosis, an endemic disease in Southeast Asia and northern Australia, and *B. mallei* is the organism that causes glanders, an equine infection seen in Asia and Africa that can be transmitted to humans. *B. gladioli* has been isolated from patients with CF, from immunocompromised people, and from high-risk neonates.[2] Other *Burkholderia* spp. can cause sporadic infections or nosocomial outbreaks in immunocompromised people but have not been associated with specific syndromes.

TABLE 156.1

Infections Caused by *Burkholderia* Species

Organism	Underlying Disease	Disease Caused	Site or Type of Infection
***Burkholderia cepacia* complex**	Cystic fibrosis Chronic granulomatous disease	Pneumonia and others	Lungs Lungs and pleura Lymph nodes Skin and soft tissue Bloodstream Septicemia
Burkholderia pseudomallei	Immunocompromised state Diabetes mellitus Renal insufficiency	Melioidosis	Septicemia Lungs Skin and soft tissue Bone
Burkholderia mallei		Glanders	Septicemia Skin Peritoneum Lymph nodes
Burkholderia gladioli	Cystic fibrosis Chronic granulomatous disease	Pneumonia and others	Lungs Lungs and pleura Lymph nodes Skin and soft tissue Bloodstream Septicemia

Burkholderia Cepacia Complex

B. cepacia is recognized as a complex of at least 20 named species, some of which can be distinguished phenotypically and others that require genotypic identification[3–7] (Box 156.1). *B. cepacia* complex primarily is a nosocomial pathogen and is relatively avirulent in the healthy host. In fact, multiple outbreaks of *B. cepacia* complex infection associated with contamination of intravenous solutions, intravascular devices, bronchoscopy equipment, and urinary catheters have resulted in minimal morbidity.[8–12] Because *B. cepacia* complex is able to grow in many commonly used disinfectants, such outbreaks are frequently associated with contaminated cleaning solutions.[13–16] Endemic *B. cepacia* complex infections in a large pediatric hospital were associated with contamination of ultrasound gel.[17] *B. cepacia* complex BSI also has been reported in children with hemoglobinopathies,[18] as well as cancer.[19] Patients with CF[20–22] and CGD[23,24] appear to be susceptible specifically to infection by *B. cepacia* complex; such infections can be fatal.

Box 156.1

Named Species Within *Burkholderia cepacia* Complex

Burkholderia ambifaria

Burkholderia anthina

Burkholderia arboris

Burkholderia cenocepacia

Burkholderia cepacia

Burkholderia contaminans

Burkholderia diffusa

Burkholderia dolosa

Burkholderia lata

Burkholderia latens

Burkholderia metallica

Burkholderia multivorans

Burkholderia pseudomultivorans

Burkholderia pyrrocinia

Burkholderia seminalis

Burkholderia stabilis

Burkholderia stagnalis sp. nov.

Burkholderia territorii sp. nov.

Burkholderia ubonensis

Virulence and Pathogenesis

Despite the virulence of *B. cepacia* complex in certain subpopulations of patients, specific mechanisms of pathogenesis have been difficult to elucidate, and they may depend on the underlying disease process.[25,26] Intracellular growth within professional phagocytes and epithelial cells and the proinflammatory activity of *B. cenocepacia* lipopolysaccharide likely contribute to pathogenesis.[27,28] Genomic, transcriptomic, and proteomic analyses have identified potential pathways involved in virulence including osmotic tolerance,[29] iron acquisition, drug efflux, adherence,[30,31] and motility.[32] These findings are supported by studies examining *B. cenocepacia* gene expression during growth in CF-affected sputum.[33]

Epidemiology

B. cepacia complex consists of ubiquitous organisms found in soil and water and is both a plant pathogen and an important organism for biologic control and bioremediation.[34] Nosocomial spread of *B. cepacia* complex most frequently occurs because of the contamination of disinfectant solutions used to clean reusable patient equipment, such as bronchoscopes and pressure transducers, or to disinfect skin.[13–16]

The molecular epidemiology of *B. cepacia* complex in CF has been well characterized; a predominant *B. cepacia* complex strain appears to occur at each CF center, and person-to-person transmission has been demonstrated.[3,35] A pathogenicity island in *B. cenocepacia* encodes the *B. cepacia* epidemic strain marker (BCESM), a transcriptional activator that has been associated with transmissibility as well as virulence.[36] The surface cable (Cbl) pilus, which binds CF mucin and is expressed by many *B. cenocepacia* strains, also has been associated with transmission in CF.[37]

Investigation of the epidemiology of *Burkholderia* in CGD found that, unlike in CF, patients are infected repeatedly with distinct strains. *B. cepacia* complex infections in CGD also involve multiple species including *B. ambifaria* and *B. metallica*.[23]

Clinical Manifestations

Nosocomial *B. cepacia* complex infections are most commonly BSIs,[38] although wound infections, urinary tract infections, and pneumonia can occur when those sites are contaminated.[17] BSI is also the most frequent infection in immunocompromised patients.[18,19] However, even in this population, patients rarely die of *B. cepacia* complex BSI.

Pulmonary infection in patients with CF usually does not have a discrete onset. Patients become culture positive for the organism late in the course of their disease, virtually always after infection with *P. aeruginosa* has been established. Patients with positive culture results for *B. cepacia* complex have 1 of the following 3 clinical patterns: (1) transient colonization and no change in the rate of pulmonary decompensation, (2) chronic colonization and a more rapid pulmonary deterioration, or (3) an unexpectedly rapid decline in clinical status that results in death.[20] Epidemiologic studies suggest that some species, including *B. cenocepacia* and *B. dolosa,* can cause more severe disease in patients with CF,[21,39] although other species are not considered nonpathogenic.

In CGD, pneumonia is the most common manifestation of *Burkholderia* infection[21,39]; lymphadenitis and bacteremic soft tissue infections have also occurred. In addition, macrophage activation syndrome with secondary hemophagocytic syndrome has been reported.[40,41] The onset of disease is insidious, with low-grade fever and malaise early in the course of disease and signs of systemic toxicity 3 to 4 weeks later. Pleural effusion has been seen in 50% of reported cases, and several patients with cavitary lesions have been described.[41,42] The organism is rarely isolated from sputum in these patients. Rather, cultures of blood, pleural fluid, and bronchoscopy and lung biopsy specimens have yielded *B. cepacia* complex.

Treatment

B. cepacia complex infections are difficult to treat because these organisms are highly resistant to antibiotics. Resistance is primarily related to limited entry of antimicrobial agents into the bacterial cell. Organisms are resistant uniformly to the aminoglycosides and polymyxin because of the intrinsic structure of the bacterial cell wall.[43] Limited outer membrane impermeability,[44] combined with induction of chromosomal β-lactamases,[45] results in frequent resistance to β-lactam antibiotics. Multiple antibiotic efflux mechanisms also have been reported in *B. cepacia* complex organisms and likely affect susceptibility to multiple unrelated agents.[46] The agents with the greatest in vitro activity against *B. cepacia* complex include minocycline, meropenem, ceftazidime, and doxycycline; however, in vitro synergy studies find very few synergistic 2-drug combinations.[47] Multiple-combination-drug bactericidal testing suggests that 2- and 3-drug combinations that include meropenem have the best in vitro activity against *B. cepacia* complex isolates,[48] although clinical correlation has not been demonstrated.[49] A placebo-controlled trial evaluated the efficacy of inhaled aztreonam for *Burkholderia* infection in CF and found that 24 weeks of continuous therapy did not improve lung function significantly.[50] Attempts at eradication of early *B. cepacia* complex infection in CF have been unsuccessful.[51]

Burkholderia Pseudomallei

B. pseudomallei is a major cause of melioidosis, an endemic infection in Southeast Asia and northern Australia. Melioidosis has also been reported sporadically from other tropical and subtropical areas including the Indian subcontinent, Central and South America, and central Africa, as well as in travelers returning from endemic areas.[52,53] Melioidosis occurs in rural populations, most commonly infecting people who have regular contact with soil and water. Infection can result from direct subcutaneous inoculation, inhalation, or ingestion through the skin. Underlying risk factors, which are rare in pediatric patients, include diabetes, heavy alcohol use, chronic pulmonary disease, renal insufficiency and thalassemia.[52] Clinical melioidosis is much less common in children than in adults.[54] However, the rate of seroconversion between the ages of 6 and 42 months has been estimated to be 24% of the population per year, and symptomatic infection can occur in children as young as 12 months of age.[55]

Melioidosis can manifest as a localized infection or as fulminant septicemia. In pediatric melioidosis, localized infection is the most common presentation (46.2%), followed by septic shock (38.4%) with or without lung involvement.[54] Localized infection in children most commonly consists of skin and soft tissue infection of the head and neck, including cervical and submandibular abscesses, suppurative parotitis, and necrotizing fasciitis.[56] Neurologic melioidosis has been reported in adults and children and is characterized by fever, headache, and ataxia.[57] Children with melioidosis and septic shock frequently have pneumonia. Multiorgan failure can occur, and in a small pediatric study, the mortality rate in patients with melioidosis and septic shock was 80%.[54] In adults, the mortality rate in septicemic melioidosis ranges from 17% to 40%, even with appropriate antimicrobial therapy.[58,59] A review of neonatal melioidosis in Thailand reported 22 cases presenting with BSI or meningitis and found a crude mortality rate of 73%.[60]

Definitive diagnosis of melioidosis is made by isolation of *B. pseudomallei* from the blood or infected site. Culture remains the gold standard for diagnosis in the absence of other commercially available tests. Serologic testing is more specific in young children than in older children and adults because of the low seroprevalence in young age groups.[55] The indirect hemagglutination antibody assay is the most commonly used serologic test, but immunochromatographic immunoglobulin M (IgM) and IgG assays have a sensitivity and specificity of 95% when both tests are used, and results can be available in <10 minutes.[61] Polymerase chain reaction detection of the *B. pseudomallei* type III secretion system in DNA extracted from clinical samples, including blood, sputum, urine, body fluids, and swabs of affected areas, has been reported to have a sensitivity of 65% and a specificity of 100%, with no polymerase chain reaction–positive results in specimens from patients without melioidosis.[62]

Treatment of melioidosis is difficult, and relapse is common.[63] *B. pseudomallei* is intrinsically resistant to the aminoglycosides and polymyxins. Agents demonstrating in vitro activity include ceftazidime, meropenem, imipenem, piperacillin-tazobactam, doxycycline, chloramphenicol, amoxicillin-clavulanate, and trimethoprim-sulfamethoxazole.[64] Treatment has 2 phases: (1) an intensive phase with 2 weeks of intravenous administration of ceftazidime, meropenem, or imipenem, followed by (2) 3 to 6 months of an oral eradication phase using trimethoprim-sulfamethoxazole to prevent relapse.[53]

Burkholderia Mallei

B. mallei is the cause of glanders, an equine infection seen primarily in the Far East and only rarely spread to humans. In the United States, a single laboratory-acquired case has been reported since 1945.[65] The organism is present in the nasal secretions and pustular drainage of infected horses and can be spread by skin or mucous membrane contact with these infected materials. The disease in humans is a severe systemic infection with ulcerative necrosis of the upper respiratory tract, cervical and mediastinal lymphadenopathy, pustular skin lesions, and pneumonia, with subsequent septicemia.[66] Without treatment, BSI caused by *B. mallei* usually is fatal within 1 to 2 weeks. Localized infection can be acute or chronic. *B. mallei* infections have been treated successfully with sulfadiazine in both humans and animals. Tetracyclines, aminoglycosides, ceftazidime, combinations of β-lactam agents and β-lactamase inhibitors, carbapenems, sulfonamides, and fluoroquinolones demonstrate activity in vitro.[64]

Burkholderia Gladioli

Because of its pigmentation and ability to grow on selective agars, *B. gladioli* frequently is misidentified as *B. cepacia* complex. *B. gladioli* can be distinguished biochemically because it is usually indophenol oxidase negative and does not produce an acid reaction on lactose- and maltose-containing media. *B. gladioli* has been isolated from the sputum of patients with CF with variable clinical impact,[67] but sometimes it is associated with severe lung disease. *B. gladioli* infections in immunocompromised children and adults also have been reported.[2,68]

Stenotrophomonas maltophilia

Jane L. Burns

Stenotrophomonas maltophilia originally was classified as *Pseudomonas* but was transferred to the genus *Xanthomonas* and subsequently to its own genus, *Stenotrophomonas,* because of its pattern of biochemical reactions and its role as a human pathogen.[1–3] *S. maltophilia* exhibits a negative indophenol oxidase reaction, and many strains require methionine for growth. A unique feature of *S. maltophilia* that can aid in its identification is a positive reaction on deoxyribonuclease (DNase) test agar.

Virulence Factors

Many potential virulence factors have been identified in *S. maltophilia*, and the organism is able to grow in biofilms; however, clinical correlation of these factors with disease has not been reported.[3] Comparative genomic analysis using a pathogenic isolate of *S. maltophilia* and a plant-associated *S. rhizophila* found that the plant pathogen was missing pathways encoding adhesins, hemolysins, exopolysaccharide synthetic proteins, heat shock protein chaperones, and antibiotic resistance mechanisms,[4] findings suggesting a possible role for these factors in human virulence.

Epidemiology

S. maltophilia is found in water sources in home and hospital environments and is associated with healthcare-related infections in patients with comorbidities.[5] *S. maltophilia* can persist in commonly used disinfectant solutions, resulting in both true infections and pseudoinfections.[3,6,7] Bloodstream infection (BSI) and pneumonia are most commonly reported, but *S. maltophilia* also causes central BSI and peritoneal dialysis catheter-associated infections, endocarditis, skin and soft tissue infections, and other nosocomial infections.[5,8–11] In a study of pediatric BSI caused by glucose nonfermenting gram-negative bacilli other than *Pseudomonas aeruginosa, S. maltophilia* was the most common pathogen, occurring in 67% of patients.[12] Risk factors associated with pediatric *S. maltophilia* BSI are listed in Box 157.1.[10] Unlike with many other gram-negative pathogens, community-associated infections are not uncommon,[5] and polymicrobial infections are typical in children.[10] In children with human immunodeficiency virus infection or malignant disease, *S. maltophilia* has been reported as an important cause of central venous catheter-associated BSIs.[13] Risk factors associated with *S. maltophilia* BSI in oncology patients include severe mucositis, diarrhea, and use of metronidazole. Several reports of cross-infections in neonatal nurseries have been published.[14,15]

Box 157.1

Risk Factors Associated With *Stenotrophomonas Maltophilia* Bloodstream Infections in Children

Malignant disease

Acquisition of infection in the community

Trimethoprim-sulfamethoxazole exposure in previous 30 days

Receipt of corticosteroids or other immunosuppressive therapy

African American race

S. maltophilia is an evolving pathogen in cystic fibrosis (CF). The prevalence of isolation of *S. maltophilia* from respiratory tract specimens in patients with CF has increased steadily since 1991; more recent data found up to a 30% prevalence among teenage and young adult patients in the US.[16] In a large cohort of children and adults with CF, an increased risk of acquisition of *S. maltophilia* was associated with younger age and greater lung function decline.[17] *S. maltophilia* is also reported to be an independent risk factor for CF pulmonary exacerbations.[18] Despite uncertainty about the impact of *S. maltophilia* on longterm pulmonary function in CF,[19,20] a significant decline in forced expiratory volume in 1 second following pulmonary exacerbation has been demonstrated.[21]

Clinical Manifestations and Treatment

Infections caused by *S. maltophilia* are not distinct from nosocomial infections caused by other gram-negative organisms, with the possible exception of hemorrhagic manifestations including ecthyma gangrenosum and pulmonary hemorrhage, which may be associated with protease activity.[22–24]

S. maltophilia is highly antibiotic resistant, making treatment difficult. The organism is intrinsically resistant to the carbapenems and aminoglycosides, and resistance to most cephalosporins and penicillins is common, with many mechanisms contributing to resistance.[3,25,26] Although trimethoprim-sulfamethoxazole has long been considered first-line therapy, resistance is increasing; surveys have reported in vitro resistance as high as 10% among European isolates.[14,26,27] Despite emerging antibiotic resistance, moxifloxacin and the tetracyclines including tigecycline remain highly active in vitro.[13,25–29] Newer therapeutic approaches include combination therapy and, for pulmonary infections, inhaled agents.[3] With the exception of trimethoprim-sulfamethoxazole, isolates from patients with CF are more resistant than are isolates from people without CF.[25]

Vibrio cholerae (Cholera)

Janell A. Routh, Almea Matanock, Eric D. Mintz

Cholera is an acute diarrheal disease with great potential for epidemic spread. For centuries cholera has caused considerable morbidity and mortality, particularly in the most impoverished areas of the world, where it remains a major public health challenge. Epidemic cholera is caused by 2 toxin-producing serogroups of the bacterium *Vibrio cholerae,* O1 or O139. When severe, cholera causes rapid loss of fluid and electrolytes, and unless volume resuscitation is prompt, death can quickly result.

Description of the Pathogen

V. cholerae is a gram-negative bacterium of the family Vibrionaceae. Somatic (O) antigens differentiate the serogroups. Epidemic cholera is caused by toxin-producing strains of serogroups O1 or O139. The horizontal acquisition of genes and expression of the transcriptional coregulated pilus (located on the *Vibrio* pathogenicity island 1) and cholera toxin carried on a bacteriophage are the primary virulence factors. Nontoxigenic and non-O1, non-O139 *Vibrio cholerae* strains can cause diarrhea and septicemia, but only toxigenic O1 and O139 have caused epidemics (see Chapter 159). *V. cholerae* O1 is further divided into 2 serotypes (Inaba and Ogawa) and 2 biotypes, classical and El Tor. During epidemics, a shift from 1 serotype to another can occur.[1,2] *V. cholerae* O139 closely resembles the El Tor biotype but, unlike *V. cholerae* O1, possesses both a capsule and a distinct lipopolysaccharide and does not agglutinate with O1 antisera.[3,4]

Microbiology

Measuring 1.4 to 2.6 μm in length, *V. cholerae i*s a curved, gram-negative bacillus with a single polar flagellum. It can be grown on a selective medium such as thiosulfate citrate bile salts sucrose (TCBS) agar that facilitates isolation. After 24 hours of incubation at 37°C, *V. cholerae* colonies grown on TCBS agar are large (2–4 mm in diameter) and yellow with opaque centers and translucent edges. The organism ferments glucose and sucrose and is oxidase positive. Presumptive identification is based on slide agglutination with O1 or O139 antiserum. Two biotypes of *V. cholerae* serogroup O1, classical and El Tor, have been defined on a genetic level. The classical biotype was predominant until the 1960s, when the El Tor biotype spread around the world, started the seventh pandemic, and gradually displaced the classical biotype. Serogroup O1 isolates react with Inaba or Ogawa antiserum; both these serotypes are found among classical and El Tor biotype strains. Confirmation of O1 and O139 isolates involves demonstration of either cholera toxin production or the presence of cholera toxin gene sequences.[5]

Virulence and Pathogenesis

Infection with toxigenic strains of *V. cholerae* O1 and O139 causes a spectrum of illness. A study in Bangladesh found that 59% of people infected with the classical biotype of *V. cholerae* O1 were asymptomatic compared with 75% of those infected with the El Tor biotype. Among people with symptomatic infection, 11% of those infected with the classical biotype compared with only 2% to 5% of those with El Tor infections were hospitalized for severe cholera. The remainder had mild or moderate illness.[6,7] Mortality rates in severe cases can reach 50% in remote regions or among populations for whom treatment is not readily available. However, with prompt and appropriate volume resuscitation, the mortality rate should be

<1%. More recently, "altered" or "atypical" strains that possess an integrated El Tor biotype phage but express the classical cholera toxin allele were described.[8,9] The classical cholera toxin genes increase toxin secretion and can lead to a more severe clinical presentation.[10]

V. cholerae O1 and O139 remain in the gastrointestinal tract and typically do not invade the bloodstream; however, some reports have been published of cholera bacteremia resulting from *V. cholerae* O139.[11,12] The voluminous secretory diarrhea of cholera results from the concerted actions of two major virulence factors: cholera toxin and the toxin coregulated pilus (TCP). Cholera toxin, a protein, is composed of an A subunit and five B subunits arranged in circular form. Once the B subunit of CT phage has bound to intestinal cells, the A subunit activates adenylate cyclase, resulting in increased intracellular concentrations of cyclic adenosine monophosphate (cAMP), which fuels secretion of sodium and chloride into the gut lumen; water follows passively. Isotonic fluid is secreted at a rate that exceeds the absorptive capacity of the colon. TCP serves as the receptor for the cholera toxin phage, mediates colonization in the intestinal tract, and mediates bacterial interactions. Three additional enterotoxins, the zona occludens toxin (ZOT),[13] accessory cholera enterotoxin (ACE),[14] and WO7 toxin15 produced by *V. cholerae* O1, have been described. Cholera toxin, a protein, is composed of an A subunit and 5 B subunits arranged in a circular form. Once the B subunit of cholera toxin phage has bound to intestinal cells, the A subunit activates adenylate cyclase, thus resulting in increased intracellular concentrations of cyclic adenosine monophosphate, which fuels secretion of sodium and chloride into the gut lumen; water follows passively. Isotonic fluid is secreted at a rate that exceeds the absorptive capacity of the colon.[16,17]

Immunity

Immunity to cholera is incompletely understood. Nonspecific defense mechanisms include gastric acidity and intestinal peristalsis. People with blood group O are particularly likely to have severe cholera, although the reason is unknown.[18,19] A study in Bangladesh found that although people with blood group O were more likely to develop severe disease once they were infected, they were less likely to become infected with *V. cholerae* O1 in the first place, a finding consistent with the hypothesis of adaptive immunity.[20] The incubation period varies with the ingested dose and gastric pH but averages 1 to 3 days, with a range of a few hours to 5 days.

Antimicrobial therapy decreases the volume and duration of diarrhea and shortens the time when *V. cholerae* is detectable in stool.[21,22] Without antimicrobial therapy, *V. cholerae* is detectable in stools for approximately 1 to 2 weeks. Prolonged carriage is rare but does occur.[23] Infection with *V. cholerae* O1 induces development of serum antibacterial (vibriocidal) and antitoxin antibodies. As with other noninvasive enteric infections, specific immunity is provided primarily by secretory immunoglobulin (immunoglobulin A), which, in the case of cholera, lasts only a few months. Cholera infection can induce long-lasting immunologic memory, but reinfection with the same or a different serogroup, biotype, or serotype is possible.[24] However, repeated infections with the same or different serogroups, biotypes, or serotypes can confer longterm immunity.[25] A study comparing the immune response of patients infected with *V. cholerae* O1 and O139 revealed that both serogroups elicit vibriocidal and cholera toxin–specific responses. However, previous infection with serogroup O1 does not offer protection against infection with serogroup O139.[26,27] Where cholera is prevalent, children who are not breastfed are infected more often than are breastfed children.[28] A mother who breastfeeds not only protects her infant from unsafe alternative food sources,[28] but also, if previously exposed to *V. cholerae,* can transfer specific immunoglobulin A antibodies in her milk.[29]

Epidemiology

Cholera can be endemic, epidemic, or pandemic. For centuries, cholera has remained endemic in countries bordering the Bay of Bengal and has spread in periodic pandemic waves. Worldwide, epidemics tend to occur during warm seasons.

The modern era of cholera comprises 7 pandemics; the first 6 occurred between 1817 and 1923. Most of these pandemics originated in Asia, usually the Indian subcontinent, and subsequently extended to Europe, the Americas, and sometimes Africa.[30] During the third pandemic, the English physician John Snow traced cholera in London to the Broad Street pump and documented waterborne disease transmission before the etiology of the disease was known. During the fifth pandemic, Robert Koch isolated *V. cholerae* from patients with diarrhea, thereby establishing the etiologic agent. Strains of the fifth and sixth pandemics were of the classical biotype.

The ongoing seventh pandemic, already the longest and most widespread, began in 1961, when *V. cholerae* O1, biotype El Tor, spread from a focus in Sulawesi (formerly Celebes), Indonesia. In 1971, it reached both East and West Africa, where it remains endemic. After more than 100 years without epidemic cholera, the pandemic reached the Americas, in January 1991, when *V. cholerae* O1 appeared in Peru and spread swiftly through much of South and Central America.[31,32] Compared with epidemics of the 19th century, attack rates were higher, but mortality rates were lower.[33,34] From 1991 through 1996, more than 1.3 million cases of cholera, and nearly 12,000 associated deaths, were reported from 20 countries in Latin America, sparing the Caribbean.[35] In stark contrast to the situation in Africa, cholera was nearly eliminated from Latin America within a decade because of investments in water and sanitation infrastructure that brought additional benefits, such as decreased infant mortality.[36,37] Cholera incidence during the Latin American epidemic correlated with infant mortality, a finding suggesting that they share a common denominator of unsafe drinking water and poor sanitation.[38] Cholera remains endemic in sub-Saharan Africa, the region with the lowest population coverage for improved water sources and sanitation, with recurrent outbreaks in several countries.[39–43]

In 2010, cholera was identified in Haiti approximately 10 months after the devastating earthquake. Haiti had no documented history of epidemic cholera.[44,45] Within 1 month of the first diagnosed cases in October 2010, cholera had reached all 10 departments in Haiti, and cases had been confirmed in the Dominican Republic and the United States.[46,47] Since the introduction of cholera to Haiti, smaller outbreaks have been reported in other Latin American countries whose isolates matched the Haiti strain. Cholera occurred in Cuba in 2012 and Mexico in 2013; both outbreaks were linked by molecular epidemiology to the Haitian epidemic. As of January 1, 2016, Haiti had reported a cumulative total of nearly 806,000 cases, nearly 477,000 hospitalizations, and nearly 9,600 deaths resulting from cholera (case-fatality rate, 1.2%). From 2011 through 2014, case counts dropped dramatically each year, with small increases in 2015 and 2016; the annual fatality rate has remained close to 1%. The decreased case counts have resulted from an international collaboration with the Haitian government to improve access to safe water and sanitation, increase clinicians' awareness and knowledge of cholera treatment, and educate the public about cholera prevention.

In the US, 111 cases of cholera were reported to the Centers for Disease Control and Prevention (CDC) from 2001 through 2011. Cholera was associated with international travel in 90 (81%) patients and was domestically acquired in 20 (18%). From October 2010 to December 2011, 40 (83%) of the 48 travel-associated cases were associated with travel to Hispaniola. Of 20 patients who acquired cholera domestically, 17 (85%) reported seafood consumption; 10 (59%) ate seafood from the US Gulf Coast.[48]

In 2015, the latest year for which data were available, 42 countries notified the World Health Organization (WHO) of a total of 172,454 cholera cases and 1034 deaths (case-fatality rate, 0.8%).[43] Of the 26 countries reporting deaths from cholera, 17 (65%) were in Africa and 8 (30%) were in the Americas. The ongoing outbreak in Hispaniola contributed 36,591 (21%) of all reported cholera cases in 2015, with another 71,176 (41%) reported from Africa. Underreporting because of concerns about the political and economic ramifications of reporting cholera cases and deaths remains a problem. However, although differences in reporting account for some of the disparity in reported cases, issues regarding water, sanitation and hygiene infrastructure, and access to basic medical care clearly play a role.[49]

In 1992, a new strain of *V. cholerae* was identified in Chennai, India. The strain did not agglutinate with O1 antiserum or with antisera to any of the other 137 previously known serogroups, and it spread rapidly to 11 countries in South Asia.[11,50] Designated *V. cholerae* O139 Bengal, it was the first non-O1 *Vibrio* to cause epidemic disease. Because immunity to *V. cholerae* O1 was not protective against this new serogroup, the proportion of adults affected was unusually high. Given the potential immunologic advantage of this relatively new serogroup, concern was expressed that the advent of *V. cholerae* serogroup O139 marked the beginning of the eighth pandemic of cholera.[38] Thus far, however, O139 has remained confined to South and Southeast Asia and only transiently displaced O1 as the dominant serogroup.[51]

Brackish aquatic environments are the natural reservoirs of both O1 and non-O1 strains of *V. cholerae.* When conditions are favorable, *V. cholerae* multiplies and can survive for years, independent of human fecal contamination, in brackish water and associated invertebrates (e.g., copepods, crabs, shrimp, and oysters). Endemic foci of *V. cholerae* O1 persist in several areas of the developed world, including the US Gulf Coast, where a unique O1 strain was first identified in 1973.[52] In the developed world, rare sporadic human cases can follow ingestion of water or undercooked shellfish.[53] However, these cases occur more commonly in travelers returning from areas where disease is epidemic.[54]

Introduction of cholera into a developing area, where the drinking water supply is not protected from human fecal contamination, can cause explosive epidemics. Infection typically follows drinking of contaminated water or consumption of food washed with, or seafood harvested from, contaminated water or food prepared by someone who is excreting *V. cholerae*.[55] Waterborne transmission of *V. cholerae* was identified in multiple investigations during the epidemics in Latin America, from contamination of municipal source water and of stored water in the home.[56] Foodborne transmission can occur through foods and beverages held at ambient temperatures for long periods of time or prepared with unsafe water or ice. Drinking water from uncovered household storage containers into which hands or objects can be introduced increases the risk of illness.[38,57] Direct person-to-person spread of cholera can occur, especially in healthcare settings[58]; however, this is not thought to be a major mode of transmission.[59]

Clinical Manifestations

The hallmark of cholera is watery diarrhea leading to varying severity of volume depletion and dehydration. Mild or moderate disease can be difficult to distinguish from disease caused by several other enteric pathogens, including enterotoxigenic *Escherichia coli* (ETEC) or rotavirus; however, severe cholera is distinctive. No other diarrheal illness produces volume depletion as rapidly as cholera. Cholera usually begins with watery, colorless diarrhea flecked with mucus (“rice-water stools”) without abdominal cramps or fever. Stools can have a mild, fishy odor. Vomiting is common, can be severe, and can precede or follow diarrhea. Patients with cholera typically do not have a fever.

In untreated severe cholera, diarrhea and vomiting usually result in volume depletion with shock in 4 to 12 hours and death in 18 hours to several days. When the disease is most severe, patients lose ≥1 L of fluid per hour and die within hours. The early signs of dehydration (thirst, tachycardia, dry mucous membranes, loss of skin turgor, and sunken eyes) are followed quickly by hypotension and anuria. Renal failure secondary to hypovolemia is reversible with volume resuscitation. Altered mental status is common but usually is mild and can consist of somnolence, restlessness, or lethargy. Very rarely, patients have abdominal distention and ileus without diarrhea; this has been called “cholera sicca,” or dry cholera.[60]

Other clinical manifestations result from electrolyte imbalances. Profuse watery diarrhea rich in potassium and bicarbonate (Table 158.1) leads to hypokalemia with arm and leg cramps and metabolic acidosis, which can increase the frequency of vomiting. Hyperglycemia, resulting from high concentrations of epinephrine, glucagon, and cortisol, is more common overall than hypoglycemia, which can occur when glycogen stores are depleted and gluconeogenesis is impaired.[61] However, children with cholera are especially prone to hypoglycemia, which can lead to convulsions and poor outcomes.[62] Fever and obtundation also are more common in children.[63] Sequelae related to fluid and electrolyte derangements, followed by hypoglycemia, are the most important life-threatening consequences of cholera. During pregnancy, cholera can be particularly severe and subsequently increases the risk for fetal and neonatal death.[64]

TABLE 158.1

Electrolyte Composition of Diarrheal Stools From People With Cholera and Composition of Rehydration Solutions

---

	Sodium (mEq/L)	Potassium (mEq/L)	Chloride (mEq/L)	Base[a] (mEq/L)	Carbohydrate

Laboratory Findings and Diagnosis

Cholera is a clinical diagnosis. Once cholera is suspected, treatment must be begun before laboratory confirmation is obtained. Cholera should be considered in any patient with profuse watery diarrhea and vomiting. Clinical suspicion should increase if these symptoms are severe in any patient who has returned from an area with epidemic cholera or who has eaten undercooked shellfish in the 5 days before the onset of illness.

Cholera is diagnosed definitively by isolation of toxigenic *V. cholerae* O1 or O139 from a stool specimen or rectal swab, which should be collected before antibiotics are given.[65] Rectal swabs should be placed in a transport medium such as Cary-Blair medium warmed to room temperature; buffered glycerol saline is not acceptable. Because *V. cholerae* rarely is isolated routinely by laboratories in the US, clinicians should alert the laboratory if cholera is suspected so that specimens can be inoculated on TCBS agar or other appropriate selective media. Isolates of *V. cholerae* should be sent to the state public health laboratory for testing with O1 and O139 antisera and then to the CDC for confirmation of serogroup and serotype and detection of the cholera toxin gene.

Antimicrobial susceptibility can be determined by disk diffusion or broth microdilution testing. Interpretive criteria have been established for ampicillin, chloramphenicol, sulfonamides, tetracycline, and trimethoprim-sulfamethoxazole.[66] Susceptibility results for tetracycline by disk diffusion are used as markers for predicting susceptibility to doxycycline. No available breakpoint values exist for disk diffusion testing for ciprofloxacin or azithromycin. Specific Clinical and Laboratory Standards Institute (CLSI) criteria should be used for interpretation of results.[66] If paired acute and convalescent phase serum samples are available, rises in vibriocidal antibody titers can confirm infection retrospectively in clinically compatible cases; however, this test is not used routinely for diagnosis of cholera. Rapid immunoassays for presumptive detection of *V. cholerae* O1 or O139 from stool for field settings and during outbreaks have been marketed,[67–70] but they do not replace culture for definitive diagnosis and do not provide an isolate for antimicrobial susceptibility testing.[71]

Nonspecific abnormalities in laboratory test results include hypoglycemia or hyperglycemia, hypercalcemia, hypermagnesemia, and hyperphosphatemia. Potassium deficit may not become apparent until the patient's metabolic acidosis is corrected. Serum sodium and chloride concentrations usually are normal or slightly decreased. The white blood cell count can be elevated. Volume depletion often results in increases in hematocrit and total serum protein concentration and can cause elevated blood urea nitrogen and serum creatinine values.

Treatment

Volume Replacement

Steps in management of children with suspected cholera are listed in Box 158.1. Rapid volume resuscitation is the cornerstone of therapy. Treatment options depend on available resources and training of healthcare providers. A simple scheme can be used to determine the severity of volume depletion and guide fluid resuscitation after acute diarrhea of any cause (Table 158.2).

Box 158.1

Management of People With Suspected Cholera

- Assess for volume depletion.

- Rehydrate with oral or intravenous fluids, or both, and monitor frequently.
- Maintain hydration: replace continuing fluid losses until diarrhea and vomiting cease.
- Consider zinc supplementation in addition to rehydration.
- Give oral antibiotics to patients with moderate but progressive volume depletion and those with severe volume depletion.
- Resume feeding with a normal diet; continue breastfeeding for infants and young children.

Modified from World Health Organization. Guidelines for Cholera Control. Geneva, World Health Organization, 1993.

TABLE 158.2

Signs and Symptoms of Dehydration in Children With Watery Diarrhea

	Degree of Dehydration		
	Mild (3%–5%)	**Moderate (6%–9%)**	**Severe (≥10%)**
OBSERVATIONS			
Mental status	Alert	Restless, irritable	Lethargic or unconscious
Thirst	Slightly increased	Moderately increased	Very thirsty or too lethargic to drink
Mucous membranes	Slightly dry	Dry	Very dry
Tears	Present	Absent	Absent
Eyes	Normal	Sunken	Very sunken and dry
EXAMINATION			
Pulse	Normal	Faster than normal	Very fast, weak, or nonpalpable
Pinched skin	Retracts rapidly	Retracts slowly	Retracts very slowly
Extremities	Warm; normal capillary refill	Delayed capillary refill	Cool, mottled
Fontanelle	Normal	Sunken	Very sunken
THERAPY	Oral rehydration	Oral or intravenous rehydration	Intravenous rehydration

Modified from World Health Organization. Guidelines for Cholera Control. Geneva, World Health Organization, 1993; and Centers for Disease Control and Prevention. The management of acute diarrhea in children: oral rehydration, maintenance, and nutritional therapy. MMWR Morb Mortal Wkly Rep 1992;41:1–20.

Theoretically, children without signs of volume depletion can be treated at home with oral rehydration solution (ORS), by using small volumes of fluid initially and then gradually increasing the amount as tolerated.[72] However, this situation is very rare because most patients with clinically recognized cases have rapid volume depletion. For patients with mild volume depletion (loss of 3%–5% of body weight), 50 mL/kg of ORS should be given in the first 2 to 4 hours of therapy. For patients with moderate volume depletion (loss of 6%–9% of body weight), 100 mL/kg of ORS should be given in the first 2 to 4 hours. In both cases, volume status is reassessed at 4 hours. If volume depletion is corrected, treatment enters the maintenance phase. If losses continue, fluid deficit is estimated again, and fluid administration is resumed.[72] ORS can be administered through the nasogastric route if the patient has mild to moderate volume depletion and cannot drink.

If volume depletion is severe (loss of ≥10% of body weight) or if patients are unable to tolerate oral rehydration because of mental status changes or intractable vomiting, intravenous therapy should be started immediately. Rapid volume resuscitation can save even patients whose pulse is not initially detectable. Ringer's lactate is the appropriate fluid in the US (see Table 158.1); normal saline is far less effective because it lacks potassium and bicarbonate. Dextrose-water solutions should not be used because they do not effectively replete volume. Ringer's lactate is infused rapidly until pulse, perfusion, and mental status return to normal. Volume status is reassessed frequently. ORS (≈5 mL/kg/hr) should be added as soon as the patient is able to drink and should replace intravenous fluids as early as is practical.

During both initial volume resuscitation and maintenance, ongoing fluid losses from stool and vomit should be replaced, initially by 10 mL/kg of ORS for each watery stool passed and 2 mL/kg for each episode of emesis. Ongoing fluid losses during maintenance therapy can be replaced with either low-sodium ORS or ORS containing 75 to 90 mEq/L of sodium accompanied by another source of low-sodium fluid (e.g., human milk, formula, or water) (see Table 158.1).[72] Urine output usually resumes within 6 to 8 hours, and ≥1 mL/kg/hr every 3 to 4 hours signifies adequate fluid administration. Additional ORS always can be administered coincident with thirst. Infants and young children should continue breastfeeding, and older children should resume a normal diet as soon as they are able.

Oral rehydration therapy is as effective as intravenous rehydration[73,74]; patients with mild to moderate volume depletion can be treated with oral solutions alone, administered in small sips to patients who are vomiting.[72] In the US, WHO ORS is available in salt packets by the case or carton (Jianas Brothers, Kansas City, Mo; 816-421-2880; http://rehydrate.org/resources/jianas.htm). When mixed with 1 L of clean water per packet, the resulting solution can be used to restore fluid and electrolyte balance in patients with cholera (see Table 158.1). A systematic review of ORS among a pediatric population found that a solution with 75 mEq/L of sodium compared with the standard solution of 90 mEq/L of sodium was associated with reduction in stool output, vomiting, and intravenous fluid use.[75] Based in part on these findings, the WHO has advocated for a solution with reduced osmolarity since 2002. The current recommended solution contains 75 mEq/L of sodium with an osmolarity of 245 mOsm/L. Ceralyte (Cera Products, Columbia, Md; 888-237-2598; http://www.ceraproductsinc.com/collections/ceralyte), and a rice-based product also is available. This glucose polymer-based ORS has been shown to result in a greater reduction of stool output than glucose-based ORS.[76] Oral solutions with sodium concentrations <75 mEq/L should not be used in the treatment of cholera. Beverages high in simple sugars such as fruit juices and energy drinks should also be avoided and can actually worsen diarrhea because of their high osmotic load.[72] For patients with altered mental status who are unable to drink sufficient quantities of ORS, use of an orogastric or nasogastric tube should be considered.[77] If ORS is not available or the patient has severe dehydration, volume resuscitation should be started immediately with intravenous fluids.

Antimicrobial Agents

Although the cornerstone of treatment for cholera is replacement of fluid volume and electrolytes, treatment with antimicrobial agents decreases the duration of illness, the volume of stool output, and the period of excretion of *V. cholerae.* In conjunction with hydration, treatment with antibiotics is recommended for moderately and severely dehydrated patients, particularly for those patients who continue to pass a large volume of stool during rehydration treatment, and for all hospitalized patients.

Single-dose doxycycline orally is recommended as the first-line treatment in adults[78]; single-dose azithromycin or ciprofloxacin can be used as effective alternatives (Table 158.3).[79] Azithromycin, as a single dose, is recommended as the first-line treatment in children and pregnant women.[80] Emerging resistance to azithromycin has been noted in Vietnam.[81] Antibiotic susceptibility patterns should be determined, particularly in outbreak settings, because antibiotic-resistant strains of *V. cholerae* are common, and antibiotic choices should be informed by susceptibility patterns in the area from which the infection was most likely obtained. Antibiotics should not be used routinely for prophylaxis, but they can be considered for outbreaks occurring in institutionalized populations.[82,83] Antidiarrheal and antispasmodic agents should not be used. Zinc supplementation, in addition to rehydration, can reduce duration and severity of cholera diarrhea, particularly in children.[84]

TABLE 158.3

Antibiotics for Treatment of Cholera[a]

Antibiotic	Dose	
	Children (mg/kg)	**Adults (mg)**
DRUG OF CHOICE		
Doxycycline (a single dose)	6	300
ALTERNATIVE FOR CHILDREN <8 YR OF AGE		
Azithromycin (single dose)	20	1000
ALTERNATIVE FOR PREGNANT WOMEN		
Azithromycin (single dose)	N/A	1000

[a] See text.

Prevention

Public Health Measures

In the developed world, water and sewage treatment makes the epidemic spread of cholera extremely unlikely, although some underserved populations may be at risk.[85] In the developing world, however, contaminated drinking water and food set the stage for epidemic cholera. Chemoprophylaxis is not recommended in the US, but in the developing world, it should be considered during outbreaks that occur in institutionalized settings, such as prisons, where antimicrobials can be administered quickly and easily to potentially exposed persons. Chemoprophylaxis of household contacts in the developing world has also been suggested.[86] However, this measure can promote development of antibiotic resistance; absent convincing evidence of benefit, it is not recommended.[87–89] Quarantine of patients and mass chemoprophylaxis have not halted epidemic cholera, and they have had harmful social, economic, and microbiologic consequences; they are not recommended as epidemic control measures. Education regarding protecting drinking water and washing hands with soap and water after defecation and before preparation or eating of food can help control a cholera epidemic, particularly if education is conducted in conjunction with distribution of household water treatment supplies and soap to populations affected and those at risk. A strategy that empowers families to disinfect drinking water with chlorine and to store this water safely in closed, narrow-mouth vessels to prevent recontamination was developed in the course of the cholera epidemic in Latin America (www.cdc.gov/safewater/).[90] This approach can reduce the introduction and spread of cholera in households and has been used widely in Africa.[91,92] Breastfeeding protects infants, whether or not the mother has immunity to *V. cholerae*.[28,29]

Vaccination

Historically, parenteral cholera vaccines have not been favored because of low efficacy and a high rate of side effects. Considerable progress has been made in development of both live and killed oral cholera vaccines since the 1980s.

Currently 2 types of oral vaccines are available in some countries, although none is licensed in the US. These vaccines include the following: (1) Dukoral (manufactured by Crucell/SBL Vaccines, Sweden) contains a mixture of heat- and formalin-killed classical and El Tor *V. cholerae* strains and a recombinant B subunit of cholera toxin (WC/rBS), which can be given to adults and children ≥2 years of age; and (2) Shanchol (manufactured by Shantha

Biotechnics, Hyderabad, India) and mORCVAX (manufactured by VABIOTECH, Hanoi, Vietnam), a modified, killed, whole-cell vaccine that contains different mixtures of strains without a cholera toxin subunit and can be administered to adults and children ≥1 year old.[93,94] Both Dukoral and Shanchol are WHO prequalified. A previously marketed oral live, attenuated single-dose vaccine, Orochol (CVD 103-HgR), was discontinued, but it may be available again in the future.[94]

When Dukoral was tested extensively in the 1980s in a field trial in Bangladesh where both El Tor and classical strains were present, it yielded a protective efficacy of 62% in the first year of the trial.[95] Efficacy waned after 2 years and was substantially lower among people of blood group O,[96] among children, and against infection with El Tor biotype as opposed to classical biotype.[97] In this cluster randomized trial in an endemic area, although vaccine coverage rates varied, herd protection was observed.[98] In a large, cluster-randomized, double-blind, placebo-controlled trial conducted in India from 2006 to 2008, Shanchol was safe and effective against clinically significant cholera with a vaccine efficacy of 65% for up to 5 years.[99–101] Shanchol is less expensive and easier to administer than Dukoral.

Given concerns about the effectiveness of cholera vaccines in areas with a high prevalence of human immunodeficiency virus (HIV) infection, a case-control study using Dukoral was conducted in a city in Mozambique with an HIV seroprevalence of >20%. Although the vaccine was found to be effective, providing 78% protection, data on HIV status were not collected from study participants.[102] Neither cholera vaccine has been approved for use in pregnant women; however, a retrospective report of women who received at least 1 dose of Dukoral during pregnancy during a mass vaccination campaign in Zanzibar found no statistically significant evidence of a harmful effect of gestational exposure. This study had insufficient power to detect infrequent events.[103]

Cholera vaccines are not recommended for the general population. Given the extremely low risk of cholera for typical US and European travelers in areas with epidemic or endemic disease, counseling about risk avoidance is more cost-effective than vaccination. However, a new vaccine, Vaxchora, was recently approved by the U.S. Food and Drug Administration and the

Advisory Committee on Immunization Practices for nonpregnant, nonbreastfeeding adults 18 to 64 years old who are traveling to an area of active cholera transmission.[104]

Vaccination should be considered in areas where cholera is endemic.[94] However, it should always be done in conjunction with the implementation of safe water, sanitation, and hygiene promotion programs. In resource-poor areas, vaccination should be targeted at children ≥2 years old. After taking into account herd immunity, cholera vaccination can be a cost-effective measure in some endemic middle- to low-resource settings.[94] The WHO endorses cholera vaccination for outbreak settings where appropriate and recommends consideration of preemptive vaccination to help prevent potential outbreaks, for example, in complex humanitarian emergencies, such as in refugee settlements.[94] However, even in stable refugee populations at risk for epidemic cholera, vaccination generally is a less cost-effective intervention than improvements in water sanitation and treatment.

Epidemiologic Investigations

Because of the potential for epidemic spread in the developing world, even a single case of cholera has important public health implications. Because many *V. cholerae* infections are mild or asymptomatic, a single recognized case often portends a larger outbreak. If a case is suspected, local public health authorities should be notified, and a search should be begun immediately to identify the source. The CDC can assist state and local health departments and other countries with these epidemiologic investigations.

Advice for Travelers

Travelers to areas where epidemic cholera occurs can prevent infection by following the precautions described for prevention of traveler's diarrhea[105,106] (Box 158.2). Additionally, a new vaccine, Vaxchora, is approved for use in nonpregnant, nonbreastfeeding adults 18 to 64 years old who are traveling to an area of active cholera transmission.[104] When simple precautions are followed, the risk of cholera is low. Nonetheless, travelers to areas with cholera who experience profuse watery diarrhea, especially if it is accompanied by vomiting, should seek medical attention immediately because prompt volume resuscitation can be lifesaving.

Box 158.2

Advice for Travelers to Areas Affected by Epidemic Cholera

Usually Safe

Cooked foods that are still hot

Fruits peeled by the traveler

Carbonated bottled water without ice

Other carbonated beverages

Beverages made with boiled water

Unsafe/Avoid

Cooked food stored at ambient temperature

Salads and raw vegetables

Raw or undercooked fish and shellfish

Food and beverages from street vendors

Unboiled or untreated water or ice

Other *Vibrio* Species

Karen K. Wong, Patricia M. Griffin

In addition to organisms that cause cholera (see Chapter 158), several other *Vibrio* species cause vibriosis. These can be divided into invasive species primarily associated with bloodstream and wound infections (e.g., *V. vulnificus*) and species that typically cause gastroenteritis (e.g., *V. parahaemolyticus*). With the exception of *V. parahaemolyticus* and *V. vulnificus* biogroup 3, these organisms rarely cause outbreaks.

Description of the Pathogens

Vibrios are bacteria of the family Vibrionaceae. They are fermentative, facultatively anaerobic, gram-negative bacilli with a single polar flagellum. Except for *V. cholerae* and *V. mimicus,* all *Vibrio* species are halophilic (salt requiring).

Possible virulence factors have been described for the nontoxigenic *Vibrio* species, including cell-associated adhesins, extracellular toxins, and proteases[1]; the actual role of these factors in disease is unknown. Some *V. cholerae* non-O1, non-O139 strains[2] and *V. mimicus* strains produce cholera toxin. Little is known about immunity against nontoxigenic vibrios.

Vibrios are free-living inhabitants of marine coastal waters and, occasionally, brackish inland lakes and streams; their presence does not indicate fecal contamination. Water surface temperatures and salinity affect concentrations of most *Vibrio* species. Most *Vibrio* infections occur during summer and fall when surface waters are relatively warm. *V. vulnificus* uses iron for growth; people with elevated iron levels are at higher risk for infection.

Epidemiology

An estimated 80,000 cases of vibriosis, including 500 hospitalizations and 100 deaths, occur in the United States yearly, with most infections in men.[3,4] The incidence of vibriosis has been increasing in the US.[5] *V. parahaemolyticus* is the most frequently identified nontoxigenic *Vibrio* species in the US, and it accounts for approximately one half of human infections; *V. alginolyticus* and *V. vulnificus* are the next most commonly identified species (Table 159.1). Vibriosis is reported more commonly from coastal than inland states.[6] Estuarine filter feeders (e.g., oysters, clams, mussels, shrimp, and crabs) can sequester and concentrate vibrios. Vibriosis often occurs in people who have consumed raw or undercooked seafood, especially shellfish.[7–9] It also can occur after exposure of a wound to seawater.[8,10] Not all cases are detected because many laboratories do not routinely use media selective for vibrios.[11,12] For decades, infections with toxigenic *V. cholerae* serogroups O1 and O139 were notifiable nationally; in 2007, infection caused by any *Vibrio* species became notifiable nationally.[13]

TABLE 159.1

Vibrio Species Most Commonly Associated With Vibriosis in the United States, 2010 to 2013

Vibrio Species	Site of Isolation			
	Blood	Stool	Wound	Percentage of Reported *Vibrio* Isolates[a] (%)
Vibrio parahaemolyticus	+	+++	+	46
Vibrio alginolyticus	+	+	+++	18
Vibrio vulnificus	+++	+	++	13
Vibrio cholerae, nontoxigenic	++	+++	++	8
Vibrio fluvialis	+	+++	++	5
Vibrio mimicus	+	+++	+	2
Grimontia (Vibrio) hollisae	+/−	+++	+	1

[a] Based on 3912 vibriosis infections reported to the Centers for Disease Control and Prevention's Cholera and Other Vibrio Illness Surveillance System, 2010 to 2013. Species constituting ≥1% of reported isolates are listed.

+++, common (51%–100% of isolates); ++, occasional (10%–50% of isolates); +, infrequent (1%–9% of isolates); +/−, rare (<1% of isolates).

Vibrio vulnificus

V. vulnificus was first described by the Centers for Disease Control and Prevention (CDC) in 1979.[14] It is the *Vibrio* species most commonly associated with life-threatening illness in the US.[6] The CDC receives reports of approximately 125 illnesses, 100 hospitalizations, and 35 deaths from *V. vulnificus* yearly.[15] It is the most lethal infection associated with raw oyster consumption.[16] *V. vulnificus* has been isolated from all coastal regions of the US.[8] The organism causes 2 major syndromes: primary bacteremia and wound infection.

Infections are classified as primary bacteremia when *V. vulnificus* is isolated from a normally sterile site and the patient has no preceding wound infection. Of patients with *V. vulnificus* primary bacteremia in the US between 1988 and 1996, 96% consumed raw oysters in the 7 days before symptoms began.[17] Almost all patients with primary bacteremia have an underlying condition, such as liver disease, malignant disease, hemochromatosis, or immunocompromise.[18,19] The CDC has issued guidance regarding the risks of consuming raw or undercooked seafood, particularly in people with underlying conditions (Box 159.1).[19a]

Box 159.1

Centers for Disease Control and Prevention Guidance Regarding *Vibrio* Infection

People should be informed that consumption of raw or undercooked seafood and open wound contact with warm seawater increase the risk of *Vibrio* infection.

People who are immunocompromised, especially those with chronic liver disease, are at highest risk for severe *Vibrio* infection.

To ensure appropriate diagnosis of infection, clinicians should request microbiologic culture with selective media when *Vibrio* is suspected.

Clinical laboratories should send all *Vibrio* isolates to their state public health laboratory for confirmation and species identification. (If a positive result of a culture-independent test was used to diagnose *Vibrio* infections, a specimen should be obtained for culture.[52])

Data from Centers for Disease Control and Prevention. *Vibrio* species causing vibriosis. 2016. https://www.cdc.gov/vibrio/index.html.

Wound infection with *V. vulnificus* typically occurs through exposure of a wound to warm seawater in adults with an underlying condition,[8,20] but it can occur rarely in healthy children. Severe wound infections with *V. vulnificus* biogroup 3 have been reported from Israel among previously healthy people handling live tilapia.[21]

Vibrio parahaemolyticus

V. parahaemolyticus is the most frequently reported cause of *Vibrio* illness in the US,[6] where it produces sporadic cases and outbreaks of gastroenteritis.[22,23] Patients frequently report eating raw oysters in the week before the onset of illness. Serogroup O4 (including O4:K12 and O4:K unknown), historically linked to shellfish in the Pacific Northwest, caused outbreaks linked to consumption of raw Atlantic Coast shellfish in 2012 and 2013.[4,24] Soft tissue infections with *V. parahaemolyticus* are rare.[25,26]

Other *Vibrio* Species

Non-O1, non-O139 *V. cholerae* strains are common inhabitants of coastal and estuarine saltwater areas, although infections have also occurred after exposure to freshwater inland lakes.[27] These organisms are isolated commonly from oysters and other shellfish, especially during warmer months. Gastroenteritis is the most common presentation; bacteremia and wound infections also occur. Non-O1 strains of *V. cholerae* can produce a polysaccharide capsule, which may explain their ability to cause invasive disease.

V. alginolyticus has become the leading cause of non–foodborne *Vibrio* infections in the US. It can cause infections of the ear, eye, nose, and sinuses, especially in younger children.[8,15] *V. mimicus*, which causes primarily gastroenteritis, is associated with raw seafood consumption.[28] *V. fluvialis* has been isolated from stool of infants, children, and young adults in Bangladesh with diarrhea.[29] *V. furnissii* has been identified in patients with gastroenteritis who consumed raw seafood or came in contact with seawater, although it is also frequently isolated from asymptomatic people.[30]

Clinical Manifestations

Vibrio vulnificus

Primary bacteremia caused by *V. vulnificus* is often fulminant, with a 61% case-fatality rate.[9] One third of patients present in shock; of these patients, 90% die, usually within 48 hours of hospitalization.[31] Most have characteristic bullous skin lesions. Necrotic ulcers can progress to necrotizing fasciitis. Thrombocytopenia is common, and disseminated intravascular coagulation can occur. Initial hypotension, hemorrhagic bullous skin lesions, leukopenia, thrombocytopenia, and low serum albumin levels predict fatal outcomes.[31–36]

Patients with *V. vulnificus* wound infections typically have fever, cellulitis with ecchymosis and bullae, swelling, and intense pain at the wound site. In severe cases, fasciitis, myositis, or secondary bacteremia can ensue. In 1 series, 17% of patients presenting with *V. vulnificus* wound infection died, with higher fatality rates in patients with underlying liver disease.[8] *V. vulnificus* has been isolated from stool of patients with gastroenteritis who consumed raw oysters.[37] The typical incubation period for any *V. vulnificus* syndrome is approximately 18 hours; incubation periods up to 10 days have been reported.[38] No long-term sequelae are expected for survivors.[39]

Vibrio parahaemolyticus

V. parahaemolyticus causes gastroenteritis characterized by diarrhea that can contain mucus or blood, abdominal cramps, nausea, and vomiting.[22] The median incubation period is 17 hours (range, 4–90 hours); symptoms typically resolve after 2 days (range, 8 hours–12 days).[22] *V. parahaemolyticus* can cause wound infections when wounds are exposed to warm seawater; these infections are less likely to cause shock, amputation, or death than are *V. vulnificus* infections.[8] Primary bacteremia comprises only 5% of *V. parahaemolyticus* cases reported.[22]

Other *Vibrio* Species

Only toxigenic *V. cholerae* O1 and O139 strains, which cause cholera epidemics, are defined by the World Health Organization as causes of cholera. Some *V. cholerae* non-O1, non-O139 strains also produce cholera toxin. *V. cholerae* non-O1, non-O139 infection can be associated with diarrhea, which ranges from mild to profuse and can be bloody, as well as abdominal cramps, fever, and vomiting.[40] These strains have been isolated from wounds exposed to seawater,[8] and they can cause primary bacteremia, usually in patients with underlying immunodeficiency, hematologic malignant disease, or cirrhosis.[40,41] Symptoms resemble those of *V. vulnificus* bacteremia but usually without bullous skin lesions. The case-fatality rate of bloodstream infections is >50%.[42]

Nontoxigenic vibrios, which include *V. cholerae* O1 and O139 strains that do not produce cholera toxin, occasionally are isolated from other body sites; infections attributed to *Vibrio* species include otitis media, otitis externa, meningitis, pneumonia, peritonitis, cholecystitis, conjunctivitis, and panophthalmitis.[8,43,44] *V. alginolyticus* and *Photobacterium (Vibrio) damselae* usually are associated with external ear and wound infections, respectively, in people exposed to saltwater. *Grimontia (Vibrio) hollisae, V. fluvialis, V. mimicus,* and nontoxigenic strains of *V. cholerae* O1 typically cause gastrointestinal tract infection.[1] Isolation of an uncommon *Vibrio* species does not prove that it is the cause of clinical symptoms; the pathogenicity of some vibrios is not clearly established.

Laboratory Findings and Diagnosis

Vibrio infection should be suspected in any patient with bacteremia, wound infection, or gastroenteritis with a history of raw shellfish consumption or exposure to saltwater or brackish water. *Vibrio* species are isolated readily from blood on sheep blood agar. Isolation from stool or wounds is best accomplished using selective media, such as thiosulfate citrate bile salts sucrose (TCBS) agar,[45] which are often not included in routine microbiologic testing of stool.[11] All pathogenic *Vibrio* species (except *Grimontia [Vibrio] hollisae*) grow on TCBS agar. Final identification is made by standard biochemical tests.[46]

Treatment

Patients with primary bacteremia require prompt supportive care, including monitoring of hemodynamic status and fluid management. Early antimicrobial therapy for *V. vulnificus* bacteremia can decrease the case-fatality rate.[31,14] Recommended therapy has consisted of trimethoprim-sulfamethoxazole in combination with an aminoglycoside for children (although organisms are not susceptible uniformly to either agent) and doxycycline in combination with a third-generation cephalosporin or fluoroquinolone for adults.[47] A single-agent regimen with a fluoroquinolone such as levofloxacin, ciprofloxacin, or gatifloxacin has been reported to be at least as effective in an animal model as combination drug regimens with doxycycline and a cephalosporin.[48] This would be an appropriate use for a fluoroquinolone in children. Patients with wound infections or necrotizing fasciitis often require prompt debridement.[49,50] Most *Vibrio* gastrointestinal infections, such as those caused by *V. parahaemolyticus*, are mild and self-limited and do not require treatment other than oral rehydration (see Chapter 158). Antibiotics such as tetracycline or ciprofloxacin can be used in patients with severe or prolonged gastrointestinal illnesses; antibiotic choice should be based on antimicrobial susceptibilities.[51]

Prevention

Although the risk of vibriosis in consumers of raw oysters is greatest during summer and fall, cases occur year round. Prevention strategies are appropriate for everyone, especially for people with certain medical conditions, including liver disease, diabetes, and immunocompromising conditions, who are at higher risk for complications and death. Effective preventive measures are as follows: (1) thoroughly cooking shellfish; (2) refrigerating cooked seafood if it is not eaten immediately; (3) preventing cross-contamination of other foods with raw seafood; and (4) avoiding exposure of open wounds or broken skin to warm saltwater, brackish water, or raw shellfish harvested from such waters.

Bartonella Species (Cat-Scratch Disease)

Jin-Young Han, Richard F. Jacobs

The genus *Bartonella* consists of more than 20 species, of which the best known is *B. henselae.* The role of *B. henselae* in most cases of cat-scratch disease has been established through serologic analysis of patients and their cats, polymerase chain reaction tests on lymph nodes and skin test antigen, and isolation of the organism from human lymph nodes and cats.[1–6] *B. quintana,* the cause of louse-borne trench fever, and *B. henselae* both have been identified as the causes of bacillary angiomatosis, bacillary peliosis, bacteremia, and endocarditis. *B. bacilliformis* is the cause of Carrión disease, and other *Bartonella* species (e.g., *B. elizabethae, B. alsatica*) have been causes of endocarditis.

Description of the Pathogen and Epidemiology

Bartonella spp. are pleomorphic, gram-negative bacilli with fastidious growth requirements. Routine cultures have low yield and typically require at least 7 days before growth can be detected. Recovery on solid agar is best achieved through inoculation onto fresh chocolate agar or heart infusion agar with 5% rabbit blood. Inoculated agar is incubated in 5% carbon dioxide at 35°C for 2 to 6 weeks. Increasingly, molecular methods are used for diagnosis.

The true incidence of cat-scratch disease in the United States is unknown, although the diagnosis is made in an estimated 22,000 ambulatory patients annually, with a national incidence of hospitalization of 0.42 in 100,000 to 0.86 in 100,000.[7,8] A slightly larger proportion of cases occurs in male patients than in female patients. Although children are more likely to be affected than adults, the disease is rare in infancy.[9] The incidence is highest in southern states and lowest in arid, western states.

The domestic cat is a major reservoir for *B. henselae* and the major vector for transmission to humans. *B. henselae* bacteremia in otherwise well-appearing cats is common and can be prolonged.[10] Studies have demonstrated that 41% of pet and impounded cats have bacteremia with *B. henselae*,[6] whereas 93% of feral cats and 75% of pet cats have been found to be seropositive.[11] Although flea-borne *(Ctenocephalides felis)* transmission of *B. henselae* from cat to cat appears to be efficient, epidemiologic data do not support the efficient transmission from cats to humans by cat fleas.[12]

A cat scratch can result in cat-scratch disease. The incubation time from the cat scratch until the appearance of lymphadenopathy is 5 to 50 days (median, 12 days). Other animals, such as dogs and monkeys, as well as inanimate objects such as pins and splinters, occasionally are associated with human infection.[13]

Cat-scratch disease is a sporadic illness with no evidence of person-to-person transmission. Even if asymptomatic, members of households in which a case has been diagnosed are more likely to be seropositive than the general population.[2] Multiple cases have occurred in families, presumably resulting from direct contact with the same animal. Several widespread outbreaks also have been described. A survey of 33 geographic regions throughout North America showed that increasing prevalence of antibody to *B. henselae* in cats paralleled increasing climatic warmth and annual precipitation.[14] Seroprevalence was highest in regions with warm, humid climates, which also have a higher incidence and severity of flea infestation of cats.

Most cases of cat-scratch disease occur in fall and winter; 71% to 93% of cases are reported from August through January.[2,7,9] Seasonality may be related to feline reproductive cycles, in combination with flea activity; that is, a cohort of kittens is born in midsummer (while flea activity is high) and is weaned in early fall.

Kittens are more commonly implicated as sources of infection than adult cats, possibly because kittens are more likely to scratch. A survey of cats indicated that seroconversion occurred during the first year of life, a finding suggesting that young cats are more likely to have active infection than older ones.[15]

Humans are the only known vertebrate hosts for *B. quintana* and *B. bacilliformis*.[16,17] The arthropod vector for *B. bacilliformis* is the sandfly.[17] The vector involved in transmission of *B. quintana* is the body louse, and the association of body lice with trench fever was recognized during World War I. Both these *Bartonella* species can produce prolonged periods of asymptomatic bacteremia, thus providing a reservoir from which the body louse and sandfly can transmit the organisms to human hosts sequentially.

Bacillary angiomatosis is a rare vasoproliferative disorder that occurs almost exclusively in severely immunocompromised people.[18,19] It also has been reported in a few apparently immunocompetent people. In patients with bacillary angiomatosis, those infected with *B. henselae* often have a history of cat exposure, but those infected with *B. quintana* do not. Bacillary peliosis occurs primarily in terminally ill patients with acquired immunodeficiency syndrome, but it also has occurred in patients with other chronic debilitating diseases, such as tuberculosis and malignant disease. Persistent or relapsing fever with bacteremia caused by *B. henselae* or *B. quintana* occurs primarily in immunocompromised people but also has been reported in immunocompetent people.[20]

Bartonella now is recognized as a significant cause of culture-negative endocarditis.[21] Cases are most often reported in adults, and >95% of cases are caused by *B. quintana* or *B. henselae*.

B. bacilliformis infection (Carrión disease) is not reported outside a restricted geographic region in the Andes mountains in western South America. Two forms of this disease are recognized: (1) the acute form, known as Oroya fever, which is a severe febrile illness with a high mortality rate; and (2) the chronic phase, known as verruca peruana, which is characterized by red, warty, vascular cutaneous lesions that resemble bacillary angiomatosis.[17]

Clinical Manifestations

Cat-Scratch Disease

Human infections with *B. henselae* can be asymptomatic or symptomatic (Fig. 160.1A to J). For symptomatic patients, regional lymphadenopathy, fever, and mild constitutional symptoms are common. Cat-scratch disease is the most common cause of chronic unilateral regional lymphadenitis in children in the US.[9,22–24] After an incubation period of 7 to 12 days, 1 or more erythematous papules 2 to 5 mm in diameter will appear at the inoculation site. This primary lesion persists for ≥1 week and then regresses spontaneously. Lymphadenitis, the hallmark of cat-scratch disease, appears at 2 to 4 weeks. A hypersensitivity-type of reaction can cause the appearance of reactivation of the primary lesion at this time.

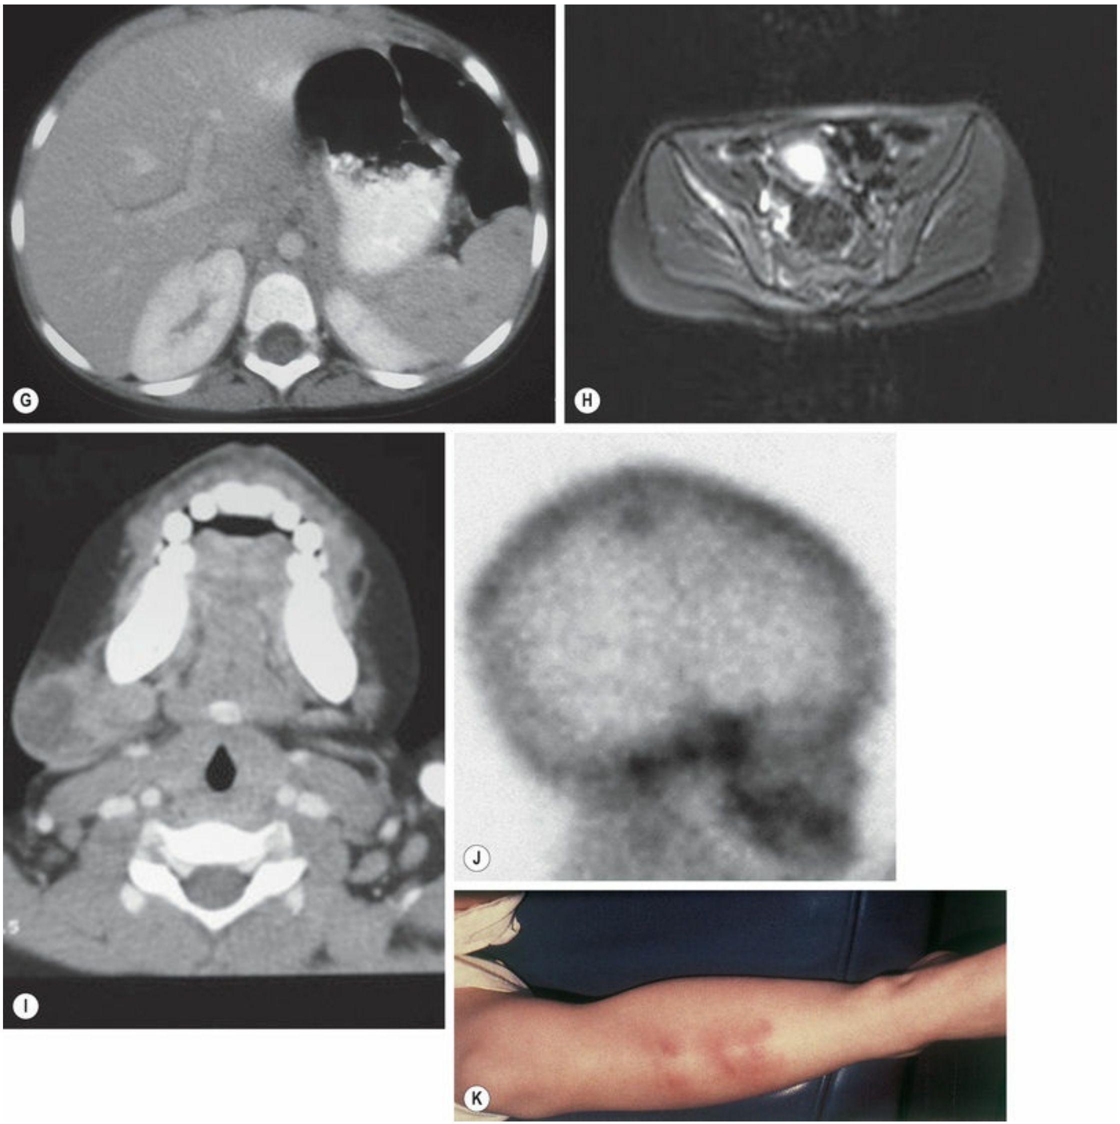

FIGURE 160.1 Typical clinical findings of *Bartonella henselae* infection (cat-scratch disease). Simple papule at the scratch site on (A) the leg of a young boy and (B) the face of a young girl. (C) Papular lesion on the arm and axillary lymphadenopathy in an adolescent. (D) Papular lesion and fluctuant, enlarged lymph nodes in the supraclavicular and neck areas of an adolescent girl who frequently cuddled her kitten over her chest and shoulder. (E) Granulomatous conjunctivitis and preauricular lymphadenopathy in a 12-year-old boy. (F) Histologic specimen of an excised neck mass showing a lymph node with granuloma and stellate microabscess (hematoxylin and eosin, 200×). (G) Computed tomography of the abdomen without contrast in a young girl with fever of unknown origin showing multiple hypodense areas in the spleen that changed minimally following administration of contrast. (H) Gadolinium-enhanced axial magnetic resonance imaging showing bone marrow enhancement of the ilium in a 6-year-old girl who came to attention for fever of unknown origin and right hip pain; no osteolytic lesion was evident on plain film. (I) Computed tomography of the neck showing a superficial necrotizing mass and (J) delayed phase of technetium-99m bone scan showing increased uptake in the skull (and ilium: not shown) in a 5-year-old girl with persistent fever and hip pain while being treated with amoxicillin for lymphadenitis; she had no signs or symptoms referable to the skull finding. (K) Erythema nodosum in a 7-year-old girl with axillary lymphadenopathy. (A, B, E, H, Copyright J.H. Brien, Scott and White Memorial Hospital,

Temple, Tex; C, D, F, K, Courtesy of S.S. Long, St. Christopher's Hospital for Children, Philadelphia, Pa; G, I, J, Courtesy of E.D. Thompson, St. Christopher's Hospital for Children, Philadelphia, Pa.)

Lymphadenitis usually involves nodes that drain the site of inoculation; however, in as many as 20% of cases, additional lymph node groups are affected. At any site of lymphadenitis, a single lymph node is involved in approximately one half of cases, and multiple nodes are involved in the remainder. The site most commonly involved is the axilla, followed by the cervical, submandibular, and inguinal areas. The area around an affected lymph node typically is tender, warm, erythematous, and indurated. In as many as 30% of cases, the affected lymph node suppurates spontaneously. Untreated, lymphadenitis usually regresses over 4 to 6 weeks.

Most patients with cat-scratch disease are afebrile and lack constitutional symptoms. When present, constitutional symptoms typically are low-grade fever, malaise, anorexia, fatigue, and headache. Parinaud oculoglandular syndrome is a distinctive presentation of cat-scratch disease in which the site of inoculation is the eyelid or conjunctiva, and a papular lesion and conjunctivitis develop at the inoculation site accompanied by ipsilateral preauricular lymphadenitis (see Fig. 160.1).

Systemic cat-scratch disease occurs in a small proportion of cases.[25] Patients with systemic cat-scratch disease typically come to medical attention for prolonged fever (1–3 weeks), malaise, listlessness, myalgia, and arthralgia; some have skin eruptions, weight loss, abdominal pain (which can be severe), peripheral lymphadenopathy, hepatomegaly, and splenomegaly. In a case series in which the presentation was fever of unknown origin, abdominal pain was present in more than one half of patients and lymphadenopathy in less than one half.[26] Using ultrasonography and computed tomography imaging, multiple microabscesses or granulomas of the liver or spleen can be identified in some cases. Other less common manifestations include encephalopathy or encephalitis, aseptic meningitis, neuroretinitis, osteolytic lesions, bone marrow granulomas, granulomatous hepatitis, pneumonia, thrombocytopenic purpura, and erythema nodosum. Patients in anecdotal cases have had demonstrable bony involvement by magnetic resonance imaging or technetium-99m bone scan, without osteolytic lesions on plain radiographs.

Other *Bartonella henselae* and *Bartonella quintana* Infections

Bacillary angiomatosis is characterized by the gradual appearance of vascular proliferative lesions of the skin and subcutaneous tissues.[18,22] These lesions can be verrucous, papular, or pedunculated, and although they usually have an erythematous base and a vascular appearance, the lesions are occasionally dry, scaly, hyperkeratotic, or plaque-like. The lesions can occur singly or in large numbers, to cover the entire body; lesions usually enlarge if untreated. Bacillary angiomatosis also can manifest either as subcutaneous nodules with or without overlying tenderness and erythema or as deep soft tissue masses.

Bacillary peliosis is characterized by the appearance of reticuloendothelial lesions in visceral organs, primarily the liver (peliosis hepatis); however, the spleen, abdominal lymph nodes, and bone marrow also can be involved. The visceral lesions of bacillary peliosis can be accompanied by the cutaneous lesions seen in bacillary angiomatosis.

Immunocompromised patients who are infected with *B. henselae* or *B. quintana* can have persistent or relapsing fever with bacteremia, frequently accompanied by weight loss and other constitutional symptoms. Patients with *Bartonella* endocarditis have clinical manifestations similar to those of other patients with subacute endocarditis.

Laboratory Findings and Diagnosis

Results of routine laboratory evaluation of patients with cat-scratch disease usually are unremarkable. The most consistently reported abnormality is an elevated erythrocyte sedimentation rate and C-reactive protein.[20,23] In disseminated disease, serum hepatic transaminase concentrations can be elevated if the liver is involved (but not in all cases of hepatic infection), and occasionally, a biliary obstructive pattern of abnormalities can be seen. Computed tomography (and, less sensitively, ultrasound) can reveal multiple round, oval, or irregular lesions 3 to 30 mm in diameter.

Several serologic tests for cat-scratch disease have been developed. Using strict clinical case criteria, immunoglobulin M

(IgM) and IgG indirect immunofluorescence antibody assays show a sensitivity of 88% and a specificity of 98%.[3,27] An enzyme immunoassay has excellent specificity (IgM, 99%; IgG, 98%).[1,2,20,28] Rates of background seropositivity (titer ≥ 1 : 64) with the immunofluorescence antibody test are low (2%–6%) but can be higher in cat owners. Demonstration of a rising IgG titer provides the best evidence of infection; however, most patients with cat-scratch disease already have high titers at the time of presentation, and titers may not fall for 2 to 6 months. In a prospective trial of antibody kinetics, enzyme immunoassay (IgM) results remained positive for 3 months and indicated acute infection. Enzyme immunoassay (IgG) antibody decreased over time, with 25% of patients remaining positive for 1 year after the onset of cat-scratch disease. No association was found between height of antibody titers or their kinetics and the clinical manifestations or duration of disease.[28] Cross-reactivity among *Bartonella* spp. is common, and serologic tests do not yet accurately distinguish among species. Western blot with cross-adsorption enables identification of specific species,[21] but the test is not readily available in the US.

If tissue specimens are obtained from patients with cat-scratch disease, attempts to isolate *Bartonella* species usually are not helpful because incubation in vitro requires 2 to 4 weeks, and for poorly understood reasons, viable organisms are rarely isolated from such patients. The histologic findings of lymph nodes or other affected tissues are characteristic but not pathognomonic. Early histologic changes consist of lymphocytic infiltrates with epithelioid granuloma formation. Later histologic changes consist of neutrophilic infiltrates within granulomas that have begun to fuse and become necrotic (stellate microabscesses) (see Fig. 160.1), followed by large, pus-filled sinuses that eventually rupture through the node capsule into surrounding tissue. Organisms can be visualized using a Warthin-Starry silver impregnation stain; however, this test is not specific for *B. henselae.*

In cases of bacillary angiomatosis and bacillary peliosis, the diagnosis usually is made by biopsy. The histologic appearance of each of these lesions is characteristic, and clusters of organisms can be demonstrated with Warthin-Starry staining. Attempts to culture *Bartonella* have been more successful in specimens collected from patients with these manifestations than in specimens collected from patients with typical cat-scratch disease.[29] Serologic tests are useful, although results are not always positive in patients with human immunodeficiency virus infection. Several procedures have been developed that are accurate and can discriminate among different *Bartonella* species in clinical tissue specimens.[30–33]

The most sensitive method of diagnosing a *B. henselae* or *B. quintana* infection is by polymerase chain reaction testing performed on various clinical specimens such as valvular tissue for endocarditis. Polymerase chain reaction results from blood samples are sometimes positive in patients with bacteremia or endocarditis.

Treatment

The management of typical cat-scratch disease primarily is supportive; the disease usually is self-limited, resolving spontaneously in 2 to 4 months. Painful suppurative lymph nodes can be treated with needle aspiration for relief of symptoms; surgical excision generally is unnecessary. *B. henselae* is susceptible in vitro to a wide range of antimicrobial agents, including penicillins, tetracyclines, macrolides, trimethoprim-sulfamethoxazole, rifampin, fluoroquinolones, aminoglycosides, and later-generation but not first-generation cephalosporins. Anecdotal reports of treatment of patients with systemic infection[25,29,34] and typical cat-scratch disease[35,36] suggest a clinical response to several antimicrobial agents, including trimethoprim-sulfamethoxazole, rifampin, ciprofloxacin, and gentamicin. A prospective, randomized, double-blind, placebo-controlled investigation of 5 days of oral azithromycin therapy for patients with serologically confirmed, typical cat-scratch lymphadenitis demonstrated a modest clinical benefit in decrease in lymph node volume as noted by ultrasound examination in the first month of therapy.[37] The value of antimicrobial therapy for patients with any form of cat-scratch disease remains uncertain.

Although the benefit of antimicrobial therapy for patients with bacillary angiomatosis or bacillary peliosis has not been studied systematically, experience suggests that such therapy is beneficial and clearly is indicated. The lesions and symptoms of these diseases respond rapidly to erythromycin or doxycycline therapy.[38] Tetracycline, minocycline, and azithromycin also have been effective.[39] Rifampin also may be effective but usually is recommended as a second drug in combination with either erythromycin or doxycycline. Patients who have only cutaneous lesions should be treated for at least 2 weeks, and those who have visceral lesions should be treated for at least 4 weeks.

Optimal therapy for *Bartonella* endocarditis is unknown; however, an aminoglycoside and doxycycline often are used.

As a systematic review demonstrated, current treatment recommendations for human bartonellosis rely mostly on personal experiences and expert opinions because of the lack of high-quality efficacy data.[40]

Complications, Sequelae, and Prognosis

Complications of cat-scratch disease are unusual. Encephalopathy is the most serious complication of cat-scratch disease, and it occurs in up to 5% of patients.[2,41] Typically, 1 to 3 weeks after the onset of lymphadenopathy (but occasionally in the absence of lymphadenopathy), the patient experiences the sudden appearance of neurologic symptoms, which can include seizures, combative or bizarre behavior, lethargy, and coma. Focal neurologic findings are unexpected. Neurologic imaging findings generally are normal, and lumbar puncture results are normal or show only slight lymphocytic pleocytosis or elevation of protein. Fever usually is absent or low grade, and systemic symptoms are minimal. The patient usually improves rapidly and spontaneously, sometimes returning to normal after a few days. In a series of 61 patients with cat-scratch encephalopathy, two thirds had fully recovered by 4 weeks, and none showed any residual encephalopathy after 1 year.[42] Cat-scratch encephalopathy should be included in the differential diagnosis of new onset status epilepticus in previously healthy school-aged children.[43]

Optic neuritis or neuroretinitis, with painless unilateral visual loss, can occur as a complication of cat-scratch disease several weeks after the onset of lymphadenopathy. Although visual loss can be profound, patients usually recover completely over a period of months. A case series of neuroretinitis documented only 3 (6%)

of 53 patients with a visual acuity of 20/200 or worse at final follow-up.[44] Peripheral neuralgia and paresthesia, as well as facial nerve palsies, also have been reported.[38] Other complications of cat-scratch disease are erythema nodosum (see Fig. 160.1K), osteolytic lesions, thrombocytopenic and nonthrombocytopenic purpura, nonimmune hemolytic anemia, atypical pneumonia, and glomerulonephritis.[45–49] Osteolytic lesions frequently are associated with a soft tissue phlegmon, can be multiple, and frequently involve unusual sites such as the spine, cranium, sternum, or fibula[47] (see Fig. 160.1).

Although acute illness caused by cat-scratch disease can be dramatic, the prognosis for all forms of this illness is excellent. Even in the absence of treatment, almost all immunocompetent patients recover fully. Reinfection appears to be extremely rare.

Bacillary angiomatosis and bacillary peliosis, even in severely immunocompromised patients, usually respond to antimicrobial therapy. However, relapses are common.

Prevention

Avoiding cats is a simple although unpopular method of preventing infections with *B. henselae*. Removing a family pet to which a case of cat-scratch disease has been attributed is unnecessary because the capacity for disease transmission appears to be transient. People with immunodeficiency should avoid contact with cats that scratch or bite, and, if obtaining a new pet, they should avoid cats younger than 1 year of age. People should wash sites of cat scratches or bites immediately, and they should not allow a cat to lick their open cuts or wounds. Control of flea infestation has the potential for limiting transmission of *B. henselae* among cats. At present, recommendations for prevention of *B. quintana* infection are limited to avoiding contact with lice and promptly eradicating lice infestation.

Key Points

Diagnosis and Management of *Bartonella henselae* Infection

Microbiology

- Slow growing, pleomorphic, gram-negative bacilli
- Fastidious growth requirements

Epidemiology

- The true incidence of human disease is unknown.
- Sporadic and asymptomatic human disease is common.
- No person-to-person transmission occurs.
- Domestic cats are the natural reservoir.
- Incidence of disease is highest in fall and winter of each year.

Diagnosis

- Routine laboratory tests usually are not helpful.
- Serologic testing is used to establish most diagnoses.
- Polymerase chain reaction performed on a clinical sample can establish the diagnosis.

Treatment

- The management of most infections is supportive.
- *Bartonella henselae* is susceptible in vitro to penicillins, tetracyclines, macrolides, trimethoprim-sulfamethoxazole, rifampin, fluoroquinolones, and aminoglycosides.
- Only azithromycin has been evaluated in a prospective, randomized, double-blind, placebo-controlled investigation; modest clinical benefit was shown for reduction in size of lymph node.
- Azithromycin therapy for cat-scratch lymphadenitis typically is 5 days.

- Only anecdotal guidance exists for treatment of systemic *B. henselae* infections.

- Optimal agents and duration of therapy for systemic infections are unknown.

Brucella Species (Brucellosis)

Edward J. Young

Brucellosis is a disease of animals that can be transmitted to humans (zoonosis).[1] The genus *Brucella* belongs to the alpha-2-subgroup of *Protobacteria* phylogenetically related to plant and other intracellular animal pathogens (e.g., *Bartonella* and *Rickettsia*).[2] Based on phenotypic analysis, 6 named (nomen) species initially were identified relating to their preferred natural hosts. Subsequently, genotypic analysis indicated a high degree of relatedness suggesting a single species with multiple biovars.[3] For epidemiologic purposes, the original nomen species classification has been retained (Table 161.1). More recently, the use of molecular techniques has expanded the number of *Brucella* spp., and more are likely to be found. Among them is a unique isolate (*B. inopinata*) from a breast implant and blood of a 71-year-old woman with no known exposure to other sources of brucellosis.[4]

TABLE 161.1

Genus *Brucella*

Nomen Species	Biovars	Preferred Hosts	Human Pathogen
Brucella abortus	1–6, 9	Cattle	Yes
Brucella melitensis	1–3	Goats, sheep	Yes
Brucella suis	1–3	Swine	Yes
	4	Caribou, reindeer	Yes
	5	Rodents	Yes
Brucella canis[a]	None	Dogs	Yes

Brucella ovis[a]	None	Sheep	No
Brucella neotomae	None	Desert wood rats	No
Brucella ceti	None	Porpoises, dolphins, whales	Yes
Brucella pinnipedialis	None	Seals	Yes
Brucella microti	None	Voles	No
Brucella inopinata	None	Unknown	Yes

[a] Signifies naturally rough strains (lacking O-polysaccharide).

Pathogen and Pathogenesis

Brucellae are small, gram-negative coccobacilli that lack endospores, capsules, or native plasmids. Their metabolism is oxidative, and all strains are aerobic, although some strains can require added carbon dioxide for primary isolation. Various media support the growth of brucellae in vitro; however, prolonged incubation (≥21 days) may be required. Rapid isolation techniques such as Bactec (Becton, Dickinson, Franklin Lakes, NJ) systems have shortened the time for primary isolation. Culture of bone marrow may have a higher yield than routine cultures of blood. *Brucella* strains are always catalase positive, but production of oxidase, urease, and hydrogen sulfide is variable. Rapid identification systems have misidentified *Brucella* as *Moraxella* spp., *Haemophilus* spp. and *Ochrobactrum* spp.[5] Because of the risk of laboratory-acquired infection, biosafety level 3 practices, containment equipment, and facilities are recommended for the handling of suspected *Brucella* cultures.[6,7]

Brucella spp. contain an unconventional cell wall lipopolysaccharide that differs from classical enterobacterial endotoxin such as *Escherichia coli*. For example, *B. abortus* lipopolysaccharide possesses a diaminoglucose backbone (rather than glucosamine); acyl groups are longer (C18–C19, C28 rather than C12 and C14) and are linked to the core by amide bonds (rather than ester and amide bonds).[8] These properties result in a lipid A with low endotoxic activity, resistance to degradation within macrophages, and protection against the host's toll-like receptor 4–mediated innate immune response.[9,10]

Brucella spp. are facultative intracellular pathogens that can survive and replicate within host phagocytic cells. Innate and acquired humoral immunity plays some role in resistance to infection; however, cell-mediated immunity is the major mechanism of recovery from brucellosis. Coincident with acquired cellular resistance, hypersensitivity to brucella antigens develops, and this may contribute to some of the clinical manifestations of the disease.

Epidemiology

Brucellosis exists worldwide but is especially prevalent in the Mediterranean basin, the Arabian peninsula, the Indian subcontinent, and in parts of Mexico, Central America, and South America. It has also reemerged in Eastern Europe, where the collapse of the former Soviet Union led to social and economic upheaval with a decline in veterinary and human health services.[11,12] Although brucellosis was once common in the United States, eradication of bovine brucellosis has reduced the incidence of human infection to <0.5 cases per 100,000 population. In states bordering Mexico, where *B. melitensis* remains enzootic in goats, brucellosis is 8 times more prevalent than elsewhere in the country, and childhood brucellosis has become an imported disease.[13]

Humans are accidental hosts, contracting the disease by direct contact with infected animals, their carcasses, or their milk. Farmers, veterinarians, abattoir workers, and laboratory personnel are at increased risk of infection. Increasingly, cases of brucellosis are linked to ingestion of fresh goat milk cheese imported from countries where the disease is enzootic. In some countries, brucellosis has been linked to the ingestion of raw camel milk or cheese[14]; consequently, people of all ages can be infected, and they may have no history of direct animal contact. In the evaluation of patients with unexplained fever, clinicians should obtain a thorough history of travel, food consumption, occupation, and avocations.[15]

The usual routes of transmission of brucellosis from animals to humans are listed in Table 161.2. Human-to-human transmission is rare, but cases of apparent venereal transfer have been reported.[16,17] Brucellosis during pregnancy poses a risk of spontaneous abortion,[18,19] and it rarely may even present a risk to hospital personnel involved in delivery.[20,21] Although rare, neonatal brucellosis has been reported, and transmission could occur through the placenta of an infected mother or by breast milk following delivery.[22,23] Once considered rare in children, brucellosis now is recognized commonly in countries where *B. melitensis* is enzootic. In such areas, fresh milk from goats and camels is fed to children, and newborn animals often share family living space, thus providing conditions favorable to transmission.[24] In countries where brucellosis is no longer common, failure of physicians to consider the diagnosis may contribute to the low reported incidence of childhood infection.[25]

TABLE 161.2

Routes of Acquisition of Brucellosis

Nomen Species	Route	Common Settings
Brucella abortus	Intracutaneous	Delivering aborting cattle or slaughtering infected animals
	Oral	Ingestion of unpasteurized milk
Brucella abortus (strain 19)	Intracutaneous	Accidental needlestick with vaccine
	Conjunctival	Accidental splash with vaccine
Brucella melitensis	Oral	Ingestion of unpasteurized milk or cheese
Brucella melitensis (strain Rev-1)	Intracutaneous	Accidental needlestick with vaccine
	Conjunctival	Accidental splash with vaccine
Brucella suis	Respiratory	Inhalation of aerosol in abattoir
	Conjunctival	Inoculation of infected blood
	Oral	Ingestion of undercooked meat, blood, or bone marrow (traditional foods)
	Intracutaneous	Slaughtering and dressing feral swine
Brucella canis	Intracutaneous	Attending aborting dogs Accidental needlestick in laboratory
	Oral	Accidental ingestion while pipetting blood or serum in laboratory

Clinical Manifestations

Brucellosis is a systemic illness characterized by nonspecific complaints with a paucity of abnormal physical findings. The onset can be insidious or acute, with symptoms generally beginning 2 to 4 weeks after exposure. Series of childhood brucellosis from countries where *B.* melitensis is endemic indicate that fever, malaise, lethargy, and joint pains are the most common complaints (Table 161.3),[26–29] and a typical presentation is a child with fever who refuses to bear weight on an extremity. Compared with adults, the lower proportion of reported general symptoms (e.g., sweats, chills, headache) in children could reflect the difficulty in obtaining accurate histories from this age group.[30]

TABLE 161.3

Clinical Findings in Childhood Brucellosis From Selected Case Series

Signs and Symptoms	Israel, 1987–1992 (N = 88)	Saudi Arabia, 1984–1995 (N = 115)	Greece, 1979–1993 (N = 52)	Turkey, 1993–2006 (N = 90)
Fever	91%	88%	88%	64%
Arthralgia	83%	73%	62%	86%
Arthritis	22%	73%	NR	7%
Headache	8%	7%	21%	NR
Sweats	5%	9%	19%	NR
Rash	7%	2%	12%	NR
Weakness or fatigue	NR	18%	29%	NR
Hepatomegaly	43%	13%	33%	16%
Splenomegaly	42%	12%	52%	11%
Lymphadenopathy	NR	2%	23%	NR

NR, not reported.

Organ Systems of Involvement

Skeletal System.

Osteoarticular involvement is common and often is the predominant manifestation of brucellosis in children.[31,32] In contrast to adults, in whom sacroiliitis predominates, childhood brucellosis most often affects large peripheral joints (knees, hips, ankles), and spondylitis is rare. Arthritis usually is accompanied by fever, malaise, weight loss, and other systemic symptoms and must be distinguished from juvenile rheumatoid arthritis. Limitation of movement with swelling and tenderness of the affected joints is prominent, similar to other forms of pyogenic arthritis.[33] Plain radiography generally is unhelpful, but ultrasound, radionuclide bone scans, and magnetic resonance imaging are useful for disclosing hip and vertebral involvement.[34,35] Synovial fluid aspiration rarely is needed unless the joint effusion is large. The fluid is exudative, and brucellae are isolated in more than one half of the cases.[36,37] In addition to pyogenic arthritis, reactive arthropathy can develop shortly after antibiotic therapy has begun, thereby raising the possibility of a Herxheimer-like reaction.[38] Most experts agree that treatment of brucellosis involving the spine should be continued for at least 3 months.[39]

Central Nervous System.

Although headache, mental inattention, and depression are common complaints in human brucellosis, invasion of the nervous system occurs in only 2% to 6% of cases.[40,41] Meningitis is the most common neurologic manifestation, and fever, headache, confusion, and cranial nerve disorders are frequent. Examination of cerebrospinal fluid reveals lymphocytic pleocytosis, elevated protein, and often hypoglycorrhachia that must be differentiated from central nervous system tuberculosis. Results of cerebrospinal fluid cultures are positive for brucellae in <50% of cases, but confirmation of neurobrucellosis can be made by demonstrating *Brucella* antibodies or antigen by agglutination, enzyme-linked immunosorbent assay, or polymerase chain reaction.[42,43] Neuroimaging in pediatric neurobrucellosis varies from normal to a variety of imaging abnormalities including inflammatory and vascular changes.[41,44] Other neurologic complications include encephalitis, myelitis, neuritis, radiculopathy, mycotic aneurysms, and brain abscess.[45] In addition to standard therapy for brucellosis, many experts recommend the addition of ceftriaxone because of its ability to achieve high concentrations in cerebrospinal fluid.[46]

Alimentary Tract.

Nausea, vomiting, anorexia, weight loss, and abdominal discomfort occur in two thirds of cases of acute brucellosis.[47] Rare cases of cholecystitis, ileitis, colitis, and pancreatitis have been reported in patients infected with *B. melitensis*.

Reticuloendothelial System.

As the largest organ of the reticuloendothelial system, the liver likely is involved in all cases; however, serum hepatic enzyme levels are elevated only mildly and can be normal. Histologically, infection with *B. abortus* has been characterized by noncaseating granulomas, whereas *B. suis* often causes suppurative abscesses. Infection with *B. melitensis* can result in a variety of hepatic lesions, most often nonspecific reactive hepatitis.[48] Rarely, chronic hepatosplenic abscesses caused by *B. melitensis* or *B. suis* can require surgical intervention for cure.[49]

Cardiovascular System.

The most common cardiovascular complication of brucellosis is endocarditis; however, this is rare in children (0.5%). Other complications include arterial and venous thrombosis, cutaneous vasculitis, and endarteritis leading to peripheral and cerebrovascular aneurysms.[50] Endocarditis most often involves the aortic valve and can occur on both native and prosthetic valves. Endocarditis was once the principal cause of death in brucellosis, but advances in diagnosis and combined medical and surgical treatments have dramatically improved the prognosis.[51] Myocarditis and pericarditis can occur with or without endocarditis.[52]

Genitourinary Tract.

Orchitis or epididymitis is relatively common in adults with brucellosis but rare in children.[53] Although *Brucella* can be recovered from urine with appropriate techniques, it generally does not compromise renal function. Nephritis or glomerulonephritis usually occurs in conjunction with endocarditis.[54]

Respiratory Tract.

Although cough is common in brucellosis, respiratory tract lesions are documented in <5% of cases in most series. Only rarely are brucellae seen on stains or grown from expectorated sputum; therefore, a definitive diagnosis depends on isolating the organism from other sites. The spectrum of pulmonary involvement is wide, including pneumonia, pulmonary nodules, and empyema.[55,56]

Hematologic System.

Mild hematologic abnormalities such as anemia, lymphocytosis, and thrombocytopenia can occur in the course of brucellosis, but they generally resolve promptly with antimicrobial therapy. Rarely, complications, such as pancytopenia, thrombocytopenic purpura, and mucosal bleeding can be life-threatening.[57,58]

Laboratory Findings and Diagnosis

A definitive diagnosis is made by recovering *Brucella* organisms from blood, bone marrow, or other tissues. In the absence of bacteriologic confirmation, a presumptive diagnosis is made by demonstrating high or rising titers of specific antibodies in serum. Various serologic methods are available, but the serum agglutination test is the standard.[59] This test measures the total quantity of *Brucella* antibodies directed against smooth lipopolysaccharide with sufficient cross-reaction to detect the major nomen species. It does not, however, differentiate among immunoglobulin classes; for this, the serum agglutination test is run in the presence of 2-mercaptoethanol, which inhibits the agglutinating activity of immunoglobulin M (IgM) without affecting IgG agglutination.[60] To detect antibodies to *B. canis*, a rough lipopolysaccharide antigen is required.[61] The immune response in brucellosis is characterized by an initial rise in IgM antibodies followed by a gradual switch to IgG synthesis. With treatment, both antibody isotypes decline over time with <5% remaining elevated after 2 years; persistent elevation of IgG antibodies presages a relapse or chronic infection.[60,62]

More recently, serologic tests based on enzyme immunoassay technology have found wide use for the detection of IgM and IgG antibodies to *Brucella* spp.[63] However, commercial enzyme immunoassays have been shown to have poor specificity for *Brucella* compared with agglutination tests, and the Centers for Disease Control and Prevention recommends that any positive result on enzyme immunoassay should be confirmed by an agglutination method.[64,65]

Among rapid point-of-care tests for *Brucella* antibodies, an immunochromatographic IgM-IgG lateral flow assay offers simplicity (a drop of blood), ease of interpretation (formation of a band), and convenience (does not require refrigeration).[66]

Polymerase chain reaction technology is advancing rapidly, but acceptance of molecular diagnostics has been slow.[67] Various primers and techniques are available to detect *Brucella* by genus, species, or biovar.[68] By using polymerase chain reaction, *Brucella* DNA has been detected in the blood of patients after the completion of apparently successful treatment, an observation that needs to be explored fully.[69]

Treatment and Outcome

Several drugs have activity in vitro against *Brucella* spp., but clinical efficacy is not always predicted by in vitro results. General recommendations for the treatment of brucellosis are listed in Table 161.4. The tetracyclines (especially doxycycline) remain the most useful drugs, and when combined with an aminoglycoside they are associated with the fewest relapses. In an attempt to find a completely oral treatment regimen, in 1986 the World Health Organization recommended the combination of doxycycline *and* rifampin administered for 45 days. Although this combination has been used successfully for uncomplicated brucellosis, it is less effective than doxycycline in combination with an aminoglycoside for focal complications such as spondylitis.[39,70] One meta-analysis (based on the results of 2 trials) recommended doxycycline *and* aminoglycoside *and* rifampin, with the aminoglycoside given for the first 7 to 14 days and with doxycycline *and* rifampin given for 6 to 8 weeks.[71]

TABLE 161.4

Recommended Therapies for Human Brucellosis

Condition	Antimicrobial Agents	Adult Dose	Route	Duration of Therapy
ADULTS				
Acute brucellosis or relapse	Doxycycline	200 mg/day	PO	6 wk
	Plus			
	Streptomycin	1 g/day	IM	2 wk
	Or			
	Gentamicin	3–5 mg/kg/day	IM or IV	1 wk
Alternative	Doxycycline	200 mg/day	PO	6 wk
	Plus			
	Rifampin	15–20 mg/kg per day	PO	6 wk
CHILDREN				
>8 years	Same as adults			
<8 years	TMP-SMX[a]	2 DS tablets/day	PO	45 days
	Plus			
	Rifampin	15–20 mg/kg/day	PO	45 days
COMPLICATIONS[b]				
Meningitis	Doxycycline	200 mg/day	PO	4–6 mo

	Plus			
	Rifampin;	900 mg/day	PO	4–6 mo
	Or			
	TMP-SMX[a]	2 DS tablets/day	PO	4–6 mo
	Plus			
	Rifampin	900 mg/day	PO	4–6 mo
Endocarditis	Same as meningitis[c]			
Pregnancy	Rifampin	900 mg/day	PO	6 wk

[a] TMP-SMX standard formulation (80 mg trimethoprim/400 mg sulfamethoxazole) is given as 4 standard tablets or 2 double-strength tablets per day.

[b] See text.

[c] Valve replacement surgery may be necessary.

DS, double-strength; IM, intramuscular; IV, intravenous; PO, by mouth; TMP-SMX, trimethoprim-sulfamethoxazole.

In the search for drugs that can be used without adverse effects in children <8 years of age, trimethoprim-sulfamethoxazole (80 mg trimethoprim/400 mg sulfamethoxazole) was initially considered satisfactory. However, subsequent controlled trials indicated a high rate of relapse when the drug was used alone. Consequently, trimethoprim-sulfamethoxazole is used in combination with rifampin for childhood brucellosis.[72,73] In addition, many fluoroquinolone antibiotics have activity in vitro against *Brucella* and are most effective when used in combination with other drugs such as rifampin.[74,75]

Osteoarticular complications rarely present special problems in treatment; however, spondylitis can require a longer course of antibiotics depending on the clinical evolution.[76] Surgical intervention may be necessary to drain pyogenic joint effusions, rare paraspinal abscesses, or chronic hepatic or splenic abscesses.

A prolonged course of therapy also may be necessary for treatment of neurobrucellosis. Multiple anti-*Brucella* agents usually are required. Although extended-spectrum cephalosporins have proved disappointing when used as monotherapy for brucellosis, some experts recommend the addition of ceftriaxone to doxycycline *in addition to* rifampin therapy despite the lack of objective evidence of benefit.[46,77,78] The use of corticosteroids as an adjunct to antibiotics may be of benefit in children with confirmed *Brucella* meningitis.[79]

Brucella endocarditis is a complication with no recognized optimal therapy; however, combinations of drugs including bactericidal agents (e.g., trimethoprim-sulfamethoxazole) have been used with success. Given the difficulties in establishing the diagnosis, surgical valve replacement often is required in addition to prolonged antibiotic therapy.

Brucellosis occurring during pregnancy can result in spontaneous abortion and in congenital and neonatal infections; however, early recognition and treatment can result in a successful outcome for mother and child.[80,81] Rifampin (900 mg once daily for 6 weeks) is the treatment of choice, whereas trimethoprim-sulfamethoxazole is an alternative after 13 weeks of gestation.

Prevention

Currently, the only licensed vaccines are veterinary products for use in domestic and semidomestic animals. Live, attenuated vaccine strains of *B. abortus* (strain 19) and *B. melitensis* (strain Rev-1) provide protection in animals but are too virulent for use in humans.[82] Another live, attenuated rough strain of *B. abortus* (strain RB51) largely has replaced strain 19 for use in cattle in the US, and although it is less virulent for humans, it is licensed only for animal use. No vaccines exist for *B. suis*, *B. canis*, or other nomen species. Children can be protected from foodborne brucellosis by ensuring pasteurization of milk and cheese and by thorough cooking of meat from susceptible animals.

Key Points

Diagnosis and Management of Brucellosis

Microbiology

- For epidemiologic purposes, pathogenic species are classified according to their preferred natural hosts: *Brucella abortus* (cattle), *B. melitensis* (goats, sheep), *B. suis* (swine), *B. canis* (dogs).

Epidemiology

- It occurs worldwide but is locally enzootic in the Mediterranean basin, Arabian peninsula, Indian subcontinent, Eastern Europe, and parts of Mexico and Central and South America.

- In the United States, the incidence of human infection is <0.5 per 100,000 population.

- Most infections result from ingestion of raw milk products from infected animals including fresh goat milk cheese.

Clinical Features

- Onset can be insidious or acute.

- Symptoms are nonspecific including fever, fatigue, and back pain.

- Any organ or system can be involved, but osteoarticular manifestations predominate.

Diagnosis

- Definitive: isolation of *Brucella* spp. from blood, bone marrow, cerebrospinal fluid, or other tissues

- Presumptive: specific antibody titer (generally >1 : 160) by standard tube agglutination test

- Detection of *Brucella* DNA in a clinical specimen by polymerase chain reaction assay

Treatment

- See Table 161.4

Bordetella pertussis (Pertussis) and Other *Bordetella* Species

Sarah S. Long, Kathryn M. Edwards, Jussi Mertsola

Pertussis is an acute respiratory tract infection that was well described in the 1500s and endemic in Europe by the 1600s; its current worldwide prevalence is dampened only by continuous use of active immunization. Sydenham first used the term *pertussis* (intense cough) in 1670. Inexorable spasms of coughing and a protracted course characterize pertussis, as attested to by names given to the disease in many languages: *tos ferina* and *tosse canina* (dog's bark) in Spanish and Italian, respectively, *chincough* (gasping cough) in old English, *coqueluche* (cock's crow) in French, and the "cough of 100 days" in Chinese.

Etiology

Bordetella pertussis is the sole cause of epidemic pertussis and the usual cause of sporadic pertussis. *B. parapertussis* contributes substantially to total cases of pertussis in Europe and accounted for approximately 5% of isolates of *Bordetella* spp. through the 1990s in the United States.[1] Using species-discriminating polymerase chain reaction (PCR) testing of respiratory samples from suspect pertussis cases from 9 states in 2008–2010,[2] and from Wisconsin in 2011–2012,[3] 14% and 6% of *Bordetella*-positive tests revealed *B. parapertussis*, respectively, sometimes found dually with *B. pertussis. B. parapertussis* typically causes milder pertussis.[4] *B. pertussis* is exclusively a human pathogen. *B. parapertussis* also has been found in lambs, but ovine and human strains are genetically distinct. *Bordetella bronchiseptica* is a common animal pathogen causing kennel cough in dogs and cats, snuffles in rabbits, and atrophic rhinitis in swine. Occasionally, *B. bronchiseptica* infects humans causing upper and lower respiratory tract infections, but endocarditis, septicemia, posttraumatic and postsurgical meningitis, and peritonitis have been reported. Typically, cases of *B. bronchiseptica* occur in immunocompromised people, patients with cystic fibrosis, or young children with exposure to infected farm animals or pets.[5–7] *Bordetella hinzii* has been recovered from blood of patients with immunodeficiency states without a respiratory illness and from sputum of patients with cystic fibrosis.[7] *Bordetella holmesii* and *B. holmesii*–like organisms have been associated with cases of bronchitis and suspected pertussis as well as septicemia, endocarditis, pericarditis, and meningitis,[8] predominantly in asplenic or immunosuppressed individuals and possibly acquired from dogs.[9–11] Of 22 patients with *B. holmesii* identified from sterile body sites in patients from 6 US states in 2010–2011, their median age was 17.1 years (youngest 1.5 years), and 64% had anatomic or functional asplenia (79% due to sickle cell disease).[12] These cases occurred during pertussis outbreaks, in which *B. holmesii* also was isolated in >10% of suspect pertussis cases. Patients with invasive *B. holmesii* did not have pertussis-like illnesses. *Bordetella petrii* caused pyogenic arthritis and osteomyelitis of the elbow in an adult after a dirt bike accident in Hawaii.[13]

Protracted coughing can be caused by *Mycoplasma* spp., adenoviruses, parainfluenza or influenza viruses, enteroviruses, and respiratory syncytial virus and *Chlamydophila pneumoniae*.[14,15]

Epidemiology

Worldwide, there are an estimated 15 million cases of pertussis annually. The World Health Organization estimates that in 2008 there were 89,000 deaths due to pertussis. During the prevaccine era in the US, pertussis was the leading cause of death from communicable disease among children younger than 14 years. During 1934–1943, an average of 200,752 cases and 4034 pertussis-related deaths were reported annually.[16] Widespread use of diphtheria and tetanus toxoid and whole cell pertussis vaccine (DTP) in the US since the late 1940s was responsible for a >100-fold decline in incidence from 110 (1922–1948) to 0.5 cases per 100,000 (1981). The 1010 cases and 7 deaths reported in 1976 in the US are the all-time lowest recorded. Incidence increased in developed countries in the 1980s related to low DTP coverage,[17,18] use of less potent vaccines,[19] or interruption of universal DTP vaccination.[20] Despite high DTP immunization rates in children younger than 7 years in the US, pertussis was increasingly recognized in 3- to 5-year cycles in the mid-1980s to 1990s, and disproportionately in adolescents and adults. By 2004, the 25,827 cases reported in the US represented the highest number since 1959 (Fig. 162.1),[21] and 34% of all US-reported cases occurred in adolescents 11 to 18 years of age (incidence ~30 per 100,000).[22] In two prospective studies using comprehensive laboratory methods, the annual incidences of prolonged undifferentiated cough illness due to pertussis in adolescents and adults were estimated to be 370 and 450 per 100,000 population, respectively.[23,24] In other studies, 12% to 32% of adolescents and young adults with prolonged cough illnesses were confirmed to have pertussis.[25,26] With development and licensure of tetanus toxoid, reduced-content diphtheria toxoid and acellular pertussis antigen vaccine (Tdap), Tdap was recommended universally in 2006 in the US at 11 to 12 years of age.[27] With 53% of US adolescents 13–18 years vaccinated by 2009, there was an approximately 50% reduction in pertussis in the age group of 11 to 19 years.[28]

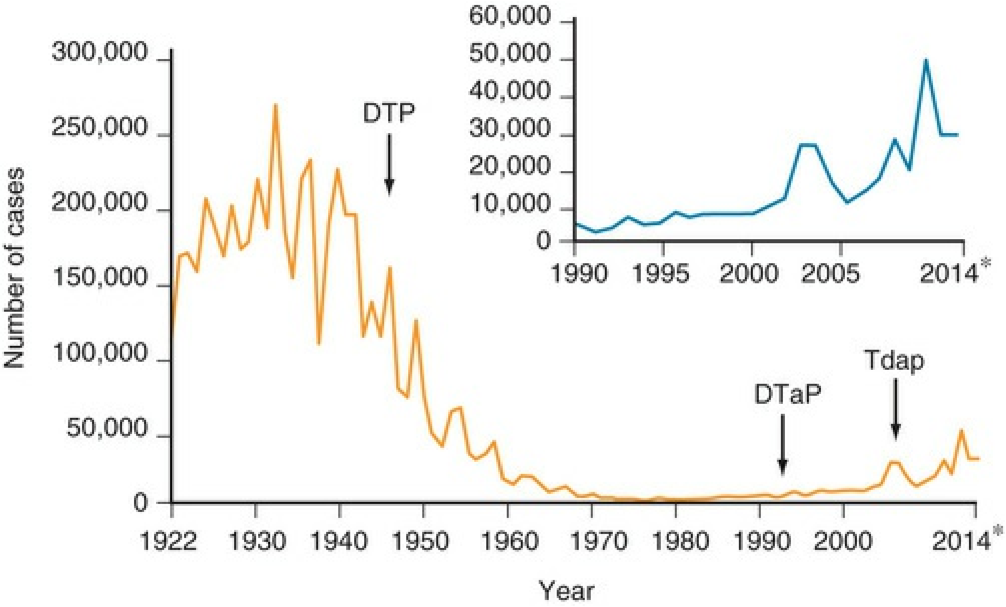

FIGURE 162.1 Annual reported cases of pertussis in the United States, 1922 through 2014. *Case numbers for 2014 are provisional. (Data from National Notifiable Diseases Surveillance System [NNDSS] for 1950 to 2014, and from passive reports to the Public Health Service for 1922 to 1949. Redrawn from Centers for Disease Control and Prevention data.)

During the prevaccine era in the US, the peak incidence of pertussis was in children 1 to 5 years of age, with infants younger than 1 year and individuals older than 10 years each accounting for less than 15% of cases.[19,20] Subclinical "boosting" reinfections and higher transplacental protection likely were responsible. However, by 1993, 44% of pertussis cases reported to the Centers for Disease Control and Prevention (CDC) occurred in children younger than 1 year. The incidence, morbidity and mortality in young infants has continued to rise (Fig. 162.2).[29] Currently, infants younger than 2 months have the highest age-related risk for pertussis (incidence ~200 per 100,000). From 2001 through 2010, 189 US deaths occurred among 27,995 reported infant cases, a case fatality ratio of 6.8/1000 infant cases.[21]

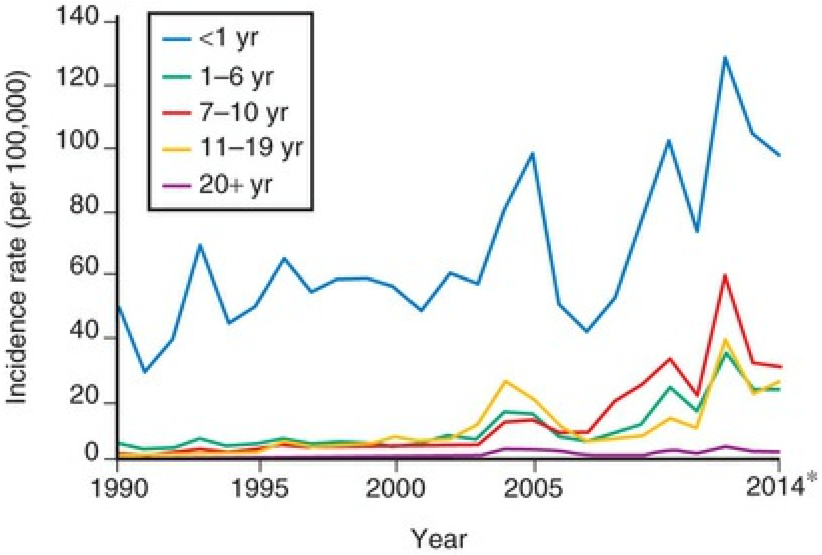

FIGURE 162.2 Age-related incidence of pertussis per 100,000 in the United States, 1990 through 2014. *Case numbers for 2014 are provisional. (Data from National Notifiable Diseases Surveillance System. Redrawn from Centers for Disease Control and Prevention data.)

Because of local and systemic reactogenicity of DTP, acellular antigen vaccines (DTaP) were developed and tested clinically, and licensed DTaP replaced DTP in the US for the reinforcing fourth and fifth doses in 1992, and for all doses in 1997. The epidemiology of pertussis has changed again in the US since 2006, likely related to use of acellular pertussis vaccines. Despite six doses of pertussis vaccine recommended between 2 months of age and adolescence, pertussis is the least well-controlled vaccine-preventable disease for which recommendations have been highly implemented.[30] More than 27,000 cases were reported in 2010, 2012, and 2014. Between 2011 and 2012, every state in the US except California reported an increase in pertussis, and the case count of 48,277 nationally in 2012 was higher than had been reported since the early 1950s.[21] After the high case rates in infants, an unusually large burden of disease was observed in age groups 7 to 10 years in 2010,[31] 13 to 14 years in 2012,[32] and 14 to 16 years in 2014, and most often in children who were fully immunized, solely with acellular pertussis vaccines.[33]

Role of Waning Immunity in Current Epidemiology

The increased incidence of pertussis in the past several decades likely is related to several overlapping factors (Fig. 162.3). Considerable evidence suggests that lack of durable protection after acellular pertussis vaccines—both DTaP and Tdap—is responsible predominantly.[34–36] Vaccine effectiveness immediately after 5 doses of DTaP is 75% to 89%[35,36] but declines each year thereafter, associated with rapidly falling antibody levels to pertussis toxin,[34–37] with odds of acquiring pertussis increasing 42% per year in one study.[37] After the last receipt of DTaP at 4 to 6 years of age, vaccine effectiveness in 8- to 12-year-olds has been estimated to be only 24%,[38] and one modeling study, assuming 85% initial protection following DTaP, estimated that only 10% of children would be protected 8.5 years later.[39] In Australia, where the fourth dose of DTaP at 18 months was discontinued in 2003, 3-year-olds currently have a greater risk for pertussis than infants.[21] Similarly, there is rapid waning of protection after Tdap, with vaccine effectiveness within the first year of >70% but only 34% 2 to 4 years after vaccination.[39,40] The abrupt return to susceptibility of immunized children aged 7 to 10 years since the mid-2000s, then of 13- to 14-year-olds in 2012 and 14- to 16-year-olds in 2014, in the US likely is due to the aging cohort of children who received acellular pertussis vaccines exclusively.[31–33,37,38,40] Observational data from Australia and the US suggest that even a distant priming effect from a single dose of DTP appears to increase durability of subsequent boosting effects of acellular vaccines[31,38,41] (Fig. 162.4).

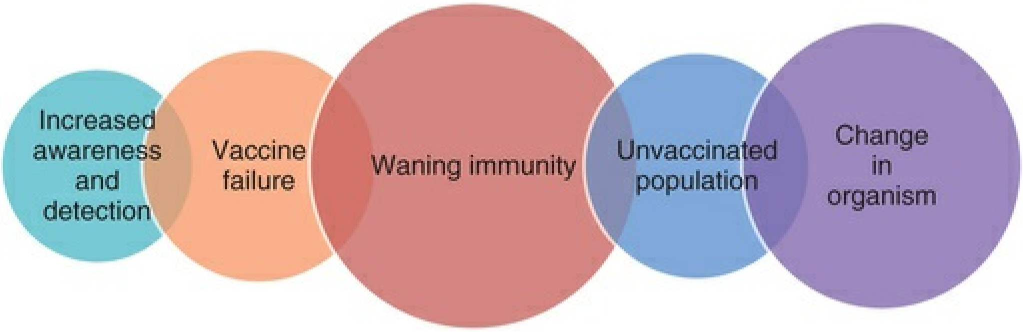

FIGURE 162.3 Schematic showing multiple factors contributing to increased incidence of pertussis.

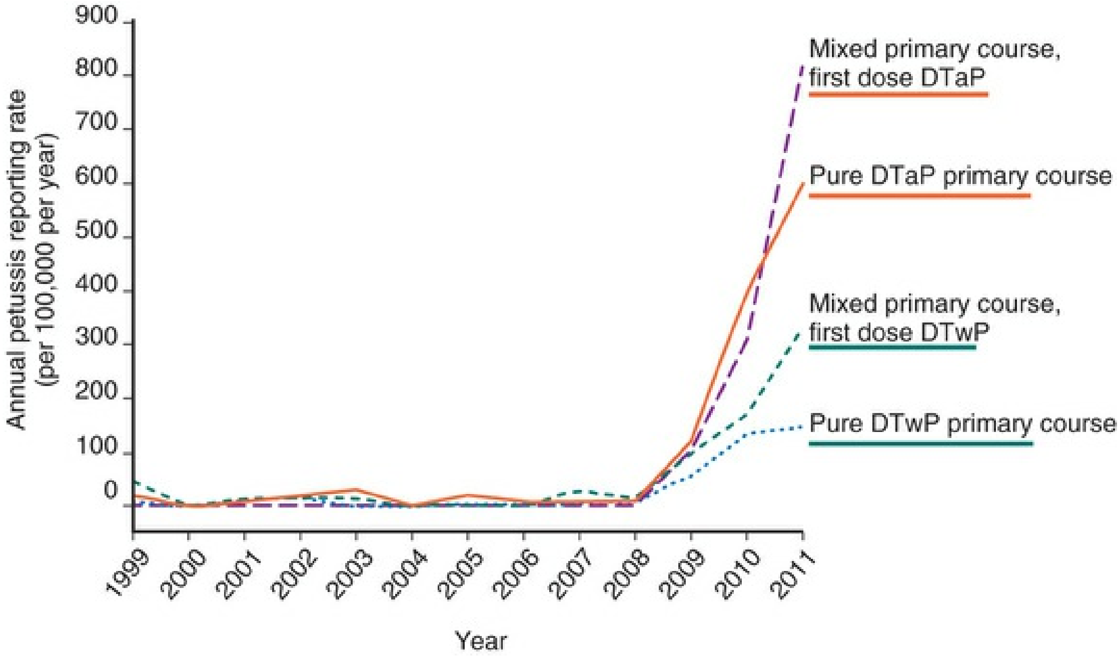

FIGURE 162.4 Reported cases of pertussis in outbreak years 2009−2011 in Queensland, Australia by receipt of primary course of DTP (whole cell pertussis vaccine) versus DTaP (acellular vaccine) for children born in 1998. Because of staggered introduction of DTaP, infants born in 1998 could have received all DTP, DTaP, or mixed vaccine primary series. (Modified from Sheridan SL, Ware RS, Grimwood K, et al. Number and order of whole cell pertussis vaccines in infancy and disease protection (letter to the editor). JAMA 2012;308:454−456.)

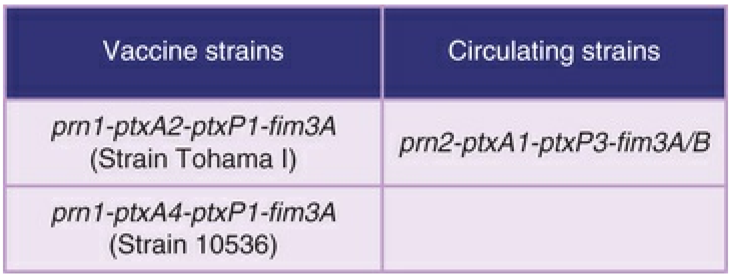
The predominant immunologic response to acellular pertussis vaccines is a type 2 helper T-lymphocyte (Th2) (antibody) response with diminished type 1 helper T-lymphocyte (Th1) (cellular) response, in contrast to a mixed Th1 and Th2 response after whole cell vaccines. Antibody titers to pertussis antigens, particularly pertussis toxin, wane quickly.[42–45] Animal studies suggest that Th17 cells are likely important in protection against pertussis, and studies in humans to assess such responses are needed.[46]

Role of Organism Adaptation in Current Epidemiology

The limited overall effect of pertussis vaccination on *B. pertussis* circulation permits pathogen adaptation, under selective pressure. Acellular vaccines licensed in the US were developed to mirror alleles of presumed virulence factors of predominant *B. pertussis* strains of previous decades as well as those included in DTPs. Divergence of circulating *B. pertussis* strains from vaccine strains began during the DTP era, with genetic adaptations occurring through allelic changes of surface proteins, including pertussis toxin, pertactin, and fimbriae, and regulation of toxin expression through the toxin promotor gene (*ptxP*).[47–53] Allelic changes were not associated with increased notification of pertussis in the US, but in the Netherlands increased cases were temporally associated with upregulation of pertussis toxin through the *ptxP3* promotor mutation.[44] Pertussis toxin is a complex bacterial toxin with an A protomer responsible for biologic activities and a B pentamer directing binding and entry of the A subunit into the cytoplasm. The *ptxA* subunit has the most potent toxic activity and is the most immunologic of the group, but allelic variants exist. Most vaccines in the US and Europe were derived from strains expressing *ptxA2* and *ptxA4*; most current circulating strains globally have the *ptxA1* allele.[45,48,50] Multiple alleles are described for *ptxP*; *ptxP1*, *ptxP2,* and *ptxP3* are predominant. The *ptxP3* largely has replaced the *ptxP1* allele worldwide and is associated with 1.6 times greater pertussis toxin production compared with *ptxP1* strains.[45,48] The *ptxP3* allele also may confer selective advantage of enhanced transmission by delaying an effective immune response and by evading complement-associated opsonophagocytosis through an autotransporter protein Vag8.[54] The two currently licensed US vaccines are *ptx1* derived (Fig. 162.5).[47–49] There has been adaptation of *B. pertussis* globally, in countries using whole cell vaccine exclusively and where acellular vaccines are used, although vaccine and circulating strains vary by country. *B. pertussis* circulating in European countries using acellular vaccines during 1998–2012 and in the US show molecular typing profiles of vaccine-divergent alleles *prn2-ptxA1-ptxP3* almost exclusively.[47,48,50,51] Fimbrial alleles show more variability, with *fim3* predominating and, in the US, transitioning from *fim3A* to *fim3B* only in the past decade during exclusive use of acellular vaccines.[48]



Vaccine strains	Circulating strains
prn1-ptxA2-ptxP1-fim3A (Strain Tohama I)	*prn2-ptxA1-ptxP3-fim3A/B*

FIGURE 162.5 Schematic showing allelic composition of US vaccine-derived and circulating strains of *Bordetella pertussis*. (Data from Schmidtke AJ, Boney KO, Martin SW, et al. Population diversity among *Bordetella pertussis* isolates, United States, 1935–2009. Emerg Infect Dis 2012;18:1248–1255.)

Since the exclusive use of acellular pertussis vaccines beginning in the late 1990s, pertactin-deficient strains have emerged, representing a small proportion of *B. pertussis* isolates in many countries, such as Japan, France, Finland, Australia, and Canada, and a large proportion of the strains in the US.[52,55–58] Pertactin-deficient strains increased rapidly in Australia from 2008–2012.[57] Pertactin-deficient *B. pertussis* strains were first reported in the US among 11 of 12 isolates from infants cases in Philadelphia in 2011 and 2012[59]; the earliest pertactin-deficient isolate in the Philadelphia collection (2007 onward) was from 2008.[60] A CDC study of isolates since 1935 showed first archived isolate of a pertactin-deficient strain from 1994, with reappearance only in 2010 and rapid increase since.[47] Pertactin-deficient *B. pertussis* strains have become predominant in outbreaks, such as in Washington State in 2012,[49] and in sporadic cases. In a retrospective study of 753 pertussis cases with isolates studied from 8 states in the US during 2011 and 2013, patients who had received at least one dose of pertussis vaccine had an adjusted odds ratio (aOR) of 2.2 (95% confidence interval [CI], 1.3–4) for having a pertactin-deficient isolate, suggesting possible selective advantage.[30] Unlike other allelic changes, pertactin-deficient strains have emerged only in countries using acellular vaccines and demonstrate multiple different gene mutations, suggesting that a number of recombinant events have occurred independently rather than that a single clone has expanded globally.[43,48,51,57]

Although pertactin is a *B. pertussis* virulence factor,[61] deficient organisms retain virulence in the mouse[45,61,62] and primate models.[63] In a mouse model, Hegerle found that pertactin-deficient isolates resist antibody-mediated cytotoxicity in vitro[45,64] and that acellular pertussis immunization provides a "fitness" advantage of sustained infection.[45] Infants with pertussis due to pertactin-deficient and pertactin-sufficient *B. pertussis* strains manifest similar illnesses.[49,60,65]

Pathogen and Pathophysiology

Pathogen

Bordetella are tiny, gram-negative coccobacilli that grow aerobically on starch-blood agar or completely synthetic media with nicotinamide supplemented for growth, amino acids for energy, and charcoal or cyclodextrin resin to absorb fatty acids and other inhibitory substances. All *Bordetella* spp. share a high degree of DNA homology among virulence genes. However, only *B. pertussis* expresses pertussis toxin.

Speciation of *Bordetella* can be based on specifically targeted PCR testing, or phenotypic characterization and direct fluorescent antibody (DFA) testing of isolates using specific antisera. Pulsed-field gel electrophoresis (PFGE) of chromosomal DNA, multilocus variable number tandem repeat analysis, multiantigen sequence typing, and whole genome sequencing of *B. pertussis* isolates from epidemiologic studies show dominance of certain strains and relatedness of epidemiologically linked cases, but diversity of strains over time and location with little evidence of geographic clustering.[54] Whole genome sequencing is the gold standard for strain differentiation but is expensive. New methodology using a single nucleotide primer extension to detect polymorphisms offers a simpler highly discriminatory alternative.[66]

Bordetella organisms elaborate a number of biologically active substances; their role in pathogenesis and protection has been reviewed by Hewlett.[67] (Table 162.1). *B. pertussis* is acquired by inhalation and has strict tropism (related to several surface molecules) for ciliated epithelium of the respiratory tract, to which infection is limited. Pertussis toxin appears to play several major roles in the pathogenesis of pertussis: facilitating attachment of *B. pertussis* to ciliated respiratory cells, contributing to cell toxicity, enhancing respiratory tract colonization by inhibiting neutrophil and monocyte migration, and delaying the induction of specific immune responses.[67] Tracheal cytotoxin, adenylate cyclase and pertactin also contribute to ciliostasis and epithelial damage.

TABLE 162.1

Components of *Bordetella pertussis* and Possible Roles in Pathogenesis and Immunity

Component	Cellular Site	Biologic Activity
Pertussis toxin (PT)	Extracellular	Facilitates attachment to ciliated respiratory epithelium
		Produces cell cytotoxicity
		Elicits lymphocytosis
		Delays induction of specific immunity
		Stimulates production of interleukin-4 and immunoglobulin E
		Inhibits migration of neutrophils and monocytes
		Causes cytopathic effect in Chinese hamster ovary cell
Filamentous hemagglutinin (FHA)	Cell surface	Facilitates attachment to ciliary respiratory epithelium
		Agglutinates erythrocytes in vivo
Pertactin (PRN)	Cell outer membrane	Facilitates attachment to ciliary respiratory epithelium
		Resists clearance by neutrophils
Agglutinogen (FIM)	Cell surface Fimbriae associated	Facilitates attachment to ciliary respiratory epithelium
Adenylate cyclase (AC) toxin	Extracytoplasmic	Inhibits phagocytic function of leukocytes
		Induces apoptosis in macrophages; catalyzes supraphysiologic production of cyclic adenosine monophosphate
		Causes hemolysis in vitro
Tracheal cytotoxin (TCT)	Extracellular	Elicits interleukin-1 and nitric oxide synthase
	Peptidoglycan-like	Causes ciliary stasis, cytopathic effect on tracheal mucosa in mice, necrosis of mouse tracheal explants

Pertussis toxin causes lymphocytosis in experimental animals by preventing their migration from the circulating blood pool. The injection of pertussis toxin intravenously into adult humans, however, was reported not to be associated with lymphocytosis.[68] Severe or fatal pertussis has been correlated with degree of lymphocytosis, a likely manifestation of pertussis toxin activity. There is no evidence of neurotoxic effects of *B. pertussis*. Although a hydrogen peroxide–detoxified pertussis toxin vaccine protects children in the short term against severe disease,[69] multiple lines of evidence support a central but not singular role for pertussis toxin.

Transmission

Pertussis is highly contagious, with attack rates of >90% in susceptible individuals exposed to aerosol droplets at close range. Chronic carriage by humans is not documented. After intense exposure, as in households and childcare facilities, the rate of subclinical infection or mild disease exceeds 50% in fully DTP immunized or naturally immune individuals.[70,71] When carefully sought, a symptomatic source case can be found for most infants.[70,71] Vaccination reduces transmissibility of *B. pertussis* even when vaccinated individuals develop symptomatic infection.[72] Although acellular pertussis vaccines protect against disease in the baboon model, they fail to prevent infection and transmission.[46]

Immunity

Neither disease, DTP, DTaP, or Tdap provides complete or lifelong immunity against reinfection or disease. There is no generally accepted laboratory correlate of protective immunity. Taken together, data suggest that high levels of antibody against pertussis toxin (PT), combinations of antibodies against multiple *B. pertussis* antigens, and cell-mediated immunity all have a role in immunity, but their precise roles remain to be determined.[69,73] Cell-mediated immune response induced by infection and whole cell vaccines can last beyond 5 years, and antibodies elicited undoubtedly include responses to many unknown antigens.[73] Acellular pertussis vaccines induce little cellular response, and antibodies elicited are against a narrow range of antigens. Antibodies begin to wane immediately after DTaP or Tdap but not immediately after whole cell vaccines or natural pertussis.[74]

Clinical Manifestations

Cadence of Symptoms

Pertussis is a prolonged disease, classically divided into catarrhal, paroxysmal, and convalescent stages, each lasting 2 weeks, but cough can persist for several months (Fig. 162.6). These stages provide useful markers for progression of disease and timing of potential complications; the duration of each, however, depends on the patient's age and immunization status, classic pertussis being seen only in unimmunized toddlers and children. In infants younger than 3 months, the catarrhal phase usually lasts a few days or is unrecognized, the paroxysmal phase is protracted, and convalescence with episodes of spasmodic cough occur throughout the first year of life. In immunized children, all stages of pertussis are foreshortened. Adults with pertussis have indistinct stages.

FIGURE 162.6 Manifestations and complications of pertussis. Duration of stages depends on patient's age and immunization status. +++, Most likely to be positive or to occur; ++, can be positive or can occur; +, occasionally positive or occurring; *DFA,* direct fluorescent antibody; *PCR,* polymerase chain reaction.

The incubation period usually is 7 to 10 (range, 5–21) days. Nondistinctive catarrhal symptoms are followed by coughing, which begins as a dry, intermittent, irritative hack and evolves into paroxysms that are the hallmark of pertussis. With insignificant provocation, the well-appearing playful toddler suddenly expresses an anxious aura and commences a machine-gun burst of uninterrupted coughs (tongue protruding, eyes bulging and watering, face reddened) on a single breath, followed by a loud whoop as inspired air traverses the still partially closed glottis. The episode may end with expulsion of a thick mucus plug. Infants younger than 3 months have heralding episodic gagging, gasping, choking, cyanosis, apnea, or a brief resolved unexplained event (BRUE) rather than paroxysmal cough; whoop generally is absent.[29,75–77] Adults describe a sudden feeling of strangulating suffocation as spasms of coughing begin. Posttussive emesis is common in pertussis at all ages and is a clue to the diagnosis in adolescents and adults.

Paroxysms progress in number and severity over days to a week and remain at peak for days to weeks, sometimes with multiple episodes hourly, before fading into convalescence when the number, severity, and duration of episodes diminish. In young infants, whoop may become louder and more classic in convalescence. Paroxysmal coughing can recur with subsequent viral respiratory illnesses over several months and is not due to reactivation of *B. pertussis*.

The physical examination between paroxysms is normal; this finding supports the diagnosis of pertussis. Fever and signs of lower respiratory tract disease generally are not seen. Conjunctival hemorrhages and petechiae on the upper body are common.

Spectrum of Symptoms

Pertussis should be suspected in any individual who has a pure or predominant complaint of paroxysmal cough that is escalating in the second week of illness. In prospective studies, nonspecific, protracted cough illness is the most frequent manifestation in adolescents and adults. In four care series in adolescents,[78–81] the following symptoms were reported: cough for >28 days, 41% to 76%; paroxysms, 82% to 100%; vomiting, 45% to 71%; whoop, 30% to 67%; cyanosis, 6% to 15%; and “apnea,” 19% to 86%. Findings with predictive value are listed in Table 162.2. Clinical case definitions for pertussis have been developed by the Council for State and Territorial Epidemiologists. A sporadic clinical case, defined as a cough illness lasting 14 or more days with at least one associated symptom of paroxysms, whoop, or posttussive vomiting with no other apparent cause, had a sensitivity of 81% and specificity of 58% using culture confirmation as the gold standard.[82] In Canadian adolescents and adults, prolonged duration of violent cough (median, 43 days) and posttussive vomiting distinguished those with pertussis from others.[83]

TABLE 162.2

Predictive Factors for Pertussis

Positive Factors	Negative Factors
Coughing contact	Fever
Incomplete immunization	Diarrhea
Years since immunization ≥3	Exanthem
Pure or predominant cough	Enanthem
Paroxysmal cough	Tachypnea
Well between paroxysms	Wheezes
Whoop	Rales
Posttussive vomiting	Lymphadenopathy
Apnea, bradycardia (infant)	Neutrophilia
Choking, gasping spells	Neutropenia
Petechiae above the clavicles	Lymphocytosis (atypical cells)
Lymphocytosis (normal cells)	

Sudden infant or unexpected death syndrome (SIDS/SUDS) is one manifestation of pertussis in young infants. Postmortem evidence of *B. pertussis* was found in 3 of 12 infants with SIDS studied in Syracuse, New York.[84] During pertussis outbreaks in the United Kingdom in the 1980s and Norway and Sweden in 1997, 3% to 5% of SIDS was associated with *B. pertussis* infection.[85,86] In a prospective study of 254 German infants with SIDS, respiratory tract specimen was positive by PCR testing for *B. pertussis* in 5% of cases.[87]

Differential Diagnosis

Other respiratory pathogens can cause pertussis-like symptoms. Adenovirus infections frequently can be distinguished from pertussis on the basis of associated features, such as fever, sore throat, and conjunctivitis, not commonly seen in pertussis. In one study, median days of cough was 18 for adenovirus infection compared with 35 days for pertussis. However, almost 50% of children with adenovirus had paroxysmal cough for >21 days, and 53% had posttussive vomiting; fewer (20%) had whooping.[14] *Mycoplasma* infection is difficult to distinguish from pertussis clinically[14,15]; if present, a history of fever, headache, and systemic symptoms at the onset of disease, and rales on auscultation, differentiate *Mycoplasma. Chlamydia trachomatis* in young infants can be distinguished by the typical staccato cough (breath with every cough), purulent conjunctivitis, tachypnea, and rales. Respiratory syncytial virus (RSV) is distinguished by wheezing and seasonal presentation. In >2000 children hospitalized with bronchiolitis whose nasal secretions were tested by PCR for *B. pertussis*, 0.2% were positive.[88] Unless the infant with pertussis has developed a secondary bacterial pneumonia, or has a dual infection with a virus, such as RSV, the physical findings between paroxysms are normal. A young infant who is being evaluated because of a history of paroxysmal cough and who appears completely well should have a paroxysm witnessed by medical personnel before disposition is planned.

Laboratory Findings and Diagnosis

Lymphocytosis (15,000 to 100,000 cells/mm^3) is characteristic in late catarrhal and paroxysmal stages of pertussis, being present in at least 75% of unvaccinated children.[89] Lymphocytes are both T and B cells and are normal small cells rather than the large atypical lymphocytes classically found in some viral infections. Lymphocytosis is uncommon in previously immunized people with pertussis.[90] Absolute increase in neutrophils or shift to immature forms suggests a secondary bacterial infection. Eosinophilia is not a feature of pertussis, even in young infants.

Lymphocytosis and thrombocytosis in young infants parallel the severity of illness. Lymphocytic leukemoid reaction or extreme thrombocytosis in infants is associated with fatal outcome.[91,92] Hypoglycemia (a PT effect) is reported only occasionally. The chest radiograph is abnormal in most hospitalized infants, showing perihilar infiltrate or interstitial edema (sometimes with a butterfly appearance) and variable atelectasis. Parenchymal consolidation suggests secondary bacterial infection. Pneumothorax, pneumomediastinum, and soft tissue air can be seen occasionally.

Culture usually is positive during the catarrhal stage and escalating paroxysmal stage in unimmunized children when proper specimen collection, transport, and methodology are used.[82] Culture is positive in <10% of immunized individuals at recognition of pertussis, those who have received macrolides or trimethoprim-sulfamethoxazole, and those who come to attention late in illness. Optimal specimen for culture is obtained by deep nasopharyngeal aspiration, nasal wash, or placing a flexible (calcium alginate– or Dacron-tipped) swab in the posterior nasopharynx for 30 seconds. Throat swab provides an inadequate specimen.[93] For short delay before inoculation, 1% casamino acid liquid medium is an acceptable transport media. Otherwise, Stainer-Scholte broth with cyclodextrin or Regan-Lowe semisolid transport medium should be used, allowing adequate recovery of organisms for up to 4 days.[82] Regan-Lowe charcoal agar with 10% horse blood and 5 to 40 μg/mL cephalexin, and Stainer-Scholte medium with cyclodextrin resins, are the preferred media for culture. Cultures are incubated at 35°C to 37°C in a humid environment (with or without 5% carbon dioxide) and should be examined with a stereoscopic microscope daily for 7 days to detect tiny glistening colonies. Culture detection is optimized by DFA testing of colonies using specific antibody for *B. pertussis* to *B. parapertussis.*

PCR testing usually is more sensitive than culture[94,95] and is the predominant method of laboratory confirmation of pertussis. In one study, only 20% of PCR-positive samples were positive by culture; culture positivity correlated with bacterial load as measured by quantitative PCR testing.[96] In adolescents and adults with pertussis, however, culture or PCR test results are positive in <10% of cases that are confirmed by serology, and especially when tests are performed >2 weeks after onset of cough.[94,95] PCR assays targeting only a single insertion sequence (IS)*481* identify *B. pertussis*, *B. holmesii,* and some strains of *B. bronchiseptica* but cannot differentiate among species and do not detect *B. parapertussis*. A *multitarget* reverse transcriptase PCR assay can detect and differentiate *B. pertussis* (including pertactin-deficient strains), *B. parapertussis,* and *B. holmesii* by targeting IS*481* and IS*1001* in *B. parapertussis* (pIS*1001*) and the IS*1001*-like element in *B. holmesii* (hIS*1001*). To confirm *B. pertussis*, a monoplex PCR for *ptxS1,* the first subunit of pertussis toxin, is used.[97]

Serologic tests using enzyme immunoassay (EIA) for detection of antibodies to components of *B. pertussis* are the most sensitive tests for diagnosis in distantly immunized individuals and those evaluated after the second week of cough, particularly adolescents and adults.[93] Serologic testing for anti-PT immunoglobulin G (IgG) antibody is the most reliable. An anti-PT IgG level of >94 EU/mL in a standardized assay has been proposed as a diagnostic cutoff point (with sensitivity of 80% and specificity of 93% using culture as the gold standard).[98] Resting anti-PT IgG level of >50 EU/mL ≥3 years after immunization is highly unusual and is supportive of pertussis disease when the clinical illness is suggestive. Antibody to PT is specific for *B. pertussis,* whereas other antibodies (e.g., pertactin and hemagglutinin) can cross-react with organisms such as *B. parapertussis, B. bronchiseptica,* and nontypable *Haemophilus influenzae.*[79,94,98] Tests for IgA and IgM antibodies to pertussis toxin lack sensitivity, specificity, and reproducibility.

Complications and Outcome

The principal complications of pertussis are apnea, secondary bacterial infections (e.g., pneumonia and otitis media), respiratory failure (from apnea, pneumonia, or pulmonary hypertension), and physical sequelae of forceful coughing. Reported rates of complications of pertussis are affected by age, immunization status, and completeness of diagnosis and reporting. Infants younger than 6 months have high morbidity and mortality, especially those younger than 3 months,[22,28,75,76] with the highest reported rates of pertussis-associated hospitalization (>90%), pneumonia (13%–25%), seizures (2%–4%), encephalopathy (0.4%–1%), and death (0.5% –1%).[22,28,99] Of 23 infants with fatal pertussis in the US reported during 1992 and 1993, 96% had pneumonia, 17% had seizures, and 13% had encephalopathy.[28] Infants intubated because of respiratory failure have a worse prognosis than those intubated because of apnea.[92]

Pertussis-related deaths are increasingly clustered among very young infants and represented 64% of deaths reported to the CDC during the 1980s and 82% in the 1990s; by 2000, all 17 pertussis-related deaths were in infants younger than 4 months.[75,100,101] With striking similarity, 94% to 100% of pertussis-related deaths reported from the United Kingdom,[101] Canada,[92] and Australia[102] since the mid-2000s were in children younger than 2 months. Other risk factors associated with death include Hispanic ethnicity in the US, multiple births, premature birth, and household source of infection.[75,91,92,100,101] Pulmonary hypertension is an increasingly recognized complication of pertussis in young infants leading to dilation of the right ventricle and respiratory failure, and usually is fatal.[76,103] Pulmonary hypertension can be misdiagnosed as pneumonia. Infants with pulmonary hypertension generally are younger than 4 weeks and frequently were born before 39 weeks of gestation. Pathologic findings identified in the respiratory tract of fatal cases, and the known physiologic responses of the infant's lung to hypoxia, suggest that *B. pertussis* triggers a cascade of events that includes pulmonary vasoconstriction, luminal aggregation of abundant leukocytes in pulmonary vessels, and compromised pulmonary blood flow; hypoxemia is exacerbated, and refractory pulmonary hypertension ensues.[98] Progression toward respiratory failure in young infants should prompt urgent evaluation, including an echocardiogram for pulmonary hypertension. High median white blood cell count was associated with pulmonary hypertension and nonsurvival in a collaborative intensive care unit study of 127 patients.[104] Only 1% to 7% of older children and adolescents are hospitalized, and complications occur in only 5%, with pneumonia and otitis media most common.[78–81,83] Individuals with underlying cardiac, pulmonary, muscular, or neurologic disorders have high risk for severe disease.

Fever, tachypnea, and respiratory distress between paroxysms, as well as absolute neutrophilia, are clues to secondary bacterial pneumonia. Expected pathogens include *Staphylococcus aureus, Streptococcus pneumoniae,* and bacteria of oropharyngeal flora.

Increased intrathoracic and intra-abdominal pressure during coughing can result in conjunctival and scleral hemorrhages (Fig. 162.7), petechiae on the upper body, epistaxis, central nervous system and retinal hemorrhages, pneumothorax and subcutaneous emphysema, umbilical and inguinal hernias, rib fracture, and urinary incontinence. Laceration of the lingual frenulum is not uncommon.

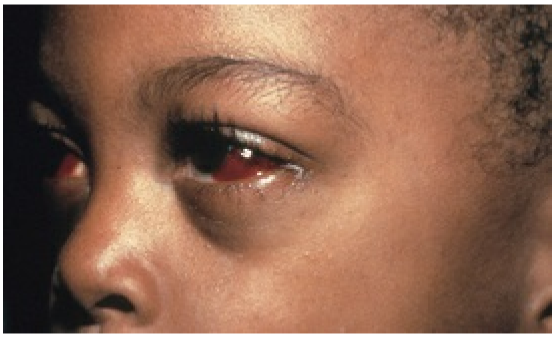

FIGURE 162.7 Bilateral scleral hemorrhages and periorbital edema in a young boy with pertussis.

Central nervous system abnormalities are almost always the result of hypoxemia or hemorrhage associated with coughing or apnea in young infants. Apnea or bradycardia or both can occur from apparent vagal stimulation or laryngospasm just before a coughing episode, from obstruction during an episode, or from hypoxemia after an episode. Occasionally, apnea or bradycardia occurs without coughing. Seizures usually are the result of hypoxemia, but hyponatremia from inappropriate secretion of antidiuretic hormone in the setting of pneumonia also should be considered.

Management

Assessment and Supportive Care

The goals of management are to limit the number of paroxysms, to observe the severity of cough and provide assistance when necessary, and to maximize nutrition, rest, and recovery. Infants younger than 3 months are admitted to the hospital almost without exception, as are many infants between 3 and 6 months of age unless witnessed paroxysms are not severe.

The specific, limited goals of hospitalization are to (1) assess progression of disease and likelihood of life-threatening events, particularly the development of pulmonary hypertension; (2) prevent or treat complications; and (3) educate parents about the natural history of the disease and the care that will be needed at home. For most infants older than 2 months without complications, goals are accomplished within a 48- to 72-hour hospitalization. Continuous electronic monitoring is performed, with alarm settings so that each paroxysm is witnessed by healthcare personnel. A detailed cough record is constructed to quantify episodes, to interpret risks and trajectory of the clinical course, and to assess safety and timing of discharge (Table 162.3). Infants whose paroxysms repeatedly lead to life-threatening events require intubation, paralysis, and ventilation. Subsequent management is challenging and should anticipate interventions because of airway obstruction, bradycardia, or cardiopulmonary complications.

TABLE 162.3

Assessment of Severity of Paroxysms During Pertussis

Clinical Assessments	Expected	Worrisome
Duration of paroxysm	<45 sec	>60 sec
Demeanor during paroxysm	Anxious, unconsolable, nondistractable; rigid; eyes bulging; tearing	Limp
Character of cough	Loud, forceful uninterrupted bursts until all air expelled	Gagging/choking/gasping > coughing
Color change	Red	Blue
Tachycardia	Resolves <30 sec after end of paroxysm	Persists
Bradycardia (<60 in infant <3 mo)	Resolves at end of paroxysm without stimulation	Persists, requires stimulation
Oxygen desaturation	Resolves <30 sec after end of paroxysm	Persists
Mucus plug	Self-expectorated	Obstructive, requires suctioning
Self-rescue breath	Immediate, large volume	Apnea or feeble attempt
Whoop	Strong	None
Posttussive state	Exhausted	Unresponsive

Mist by tent is useful for some infants with thick tenacious secretions and irritable airways. The benefit of a quiet, low-lit, undisturbed, and comforting environment cannot be overestimated or forfeited by the desire to monitor and intervene. Feeding children with pertussis is challenging. The risk for precipitating cough by nipple feeding does not warrant the use of nasoenteral or parenteral alimentation in most infants. However, large-volume feedings should be avoided.

Therapeutic Agents

Antimicrobial Agents

In vitro, *B. pertussis* is susceptible to erythromycin, newer macrolides, fluorquinolones, third-generation cephalosporins, and meropenem.[105] Ampicillin, rifampin, and trimethoprim-sulfamethoxazole are modestly active, but first- and second-generation cephalosporins are not. Rare isolates of erythromycin-resistant *B. pertussis* have been identified in children who had prolonged symptoms despite erythromycin therapy.[106–108] A few macrolide-resistant *B. pertussis* strains were found in China in 2012.[109] Recent strains, including pertactin-producing and pertactin-deficient isolates, have retained macrolide susceptibility.[110] In vitro, *B. parapertussis* is less susceptible to all agents except macrolides. *B. bronchiseptica* is most susceptible to antipseudomonal penicillins, aminoglycosides, fluoroquinolones, and tetracycline (with antagonism demonstrated between the last two drugs); erythromycin resistance is not uncommon.[5] *B. holmesii* is most susceptible to fluoroquinolones and carbapenems.[11] Use of agents with proven activity in vitro does not necessarily correlate with observable clinical benefit.

An antimicrobial agent always should be given when pertussis is suspected or confirmed in infants within 6 weeks after cough onset and in persons older than 1 year within 21 days after cough onset[111,112] (Table 162.4). There is excess risk for infantile hypertrophic pyloric stenosis (IHPS) associated with macrolide use in infants 42 days or younger,[113,114] which is highest at 14 days or younger in term infants and with erythromycin (aOR, 13.3; 95% CI, 6.8–25.9) compared with azithromycin (aOR, 8.3; 95% CI, 2.6–26).[115] In one reported experience of azithromycin use in 58 neonates, IHPS did not occur.[116] In another report, 2 of 3 triplets born at 32 weeks of gestation who were given azithromycin for 5 days at 7 weeks of age developed IHPS at 12 and 13 weeks of age, respectively.[117] Despite risk, neonates always should be given azithromycin for pertussis disease or exposure, with vigilance for IHPS.

TABLE 162.4

Recommended Antimicrobial Agents for Treatment and Postexposure Prophylaxis of Pertussis

	Age Group			
Agents	**<1 mo**	**1–5 mo**	**≥6 mo and Children**	**Adults**
PRIMARY AGENTS				

Azithromycin	Recommended agent 10 mg/kg, once daily × 5 days	10 mg/kg once daily × 5 days	10 mg/kg (max 500 mg) once on day 1; then 5 mg/kg (max 250 mg) once on days 2–5	500 mg once on day 1; then 250 mg once on days 2–5
Clarithromycin	Not recommended	15 mg/kg/day divided twice daily × 7 days	15 mg/kg/day (max 1 g/day) divided twice daily × 7 days	1 g/day divided twice daily × 7 days
Erythromycin	Not preferred	40–50 mg/kg/day divided 4 times daily × 14 days	40–50 mg/kg/day (max 2 g/day) divided 4 times daily × 14 days	2 g/day divided 4 times daily × 14 days
ALTERNATE AGENT				
TMP-SMX	Contraindicated	Contraindicated at age <2 months. At ≥2 months, TMP 8 mg/kg/day + SMX 40 mg/kg/day divided twice daily × 14 days	TMP 8 mg/kg/day + SMX 40 mg/kg/day (max TMP 320 mg/day) divided twice daily × 14 days	TMP 320 mg/day + SMX 1600 mg/day divided twice daily × 14 days

TMP-SMX, trimethoprim-sulfamethoxazole.

Modified from Tiwari T, Murphy TV, Moran J, et al. National Immunization Program. Centers for Disease Control and Prevention. Recommended antimicrobial agents for treatment and postexposure prophylaxis of pertussis. MMWR Recomm Rep 2005;54(RR-14):1–13.

Clinical efficacy of antimicrobial therapy is most evident in young infants and others who come to medical attention quickly[118]; otherwise the purpose of therapy is to eliminate contagiousness. Infants younger than 6 months (and other incompletely immunized children) have higher density and duration of colonization. Azithromycin dose is 10 mg/kg per day for 5 days.[111,112] In clinical studies, macrolides are superior to amoxicillin for eradication of *B. pertussis.* In those 2 months and older who are intolerant of macrolides, trimethroprim-sulfamethoxazole is the alternative agent.[111] Alternative therapies are not well studied. Patients with pertussis and pneumonia should be treated with one or more antibiotics in addition to a macrolide, such as ampicillin-sulbactam or cefotaxime (with additional consideration of methicillin-resistant *S. aureus* where prevalent).

Other Therapies

No randomized, blinded clinical trial of sufficient size has been performed to evaluate corticosteroids for pertussis, and their use is not warranted. A handful of small clinical trials suggest a modest reduction in symptoms with the use of aerosolized albuterol. However, one small study showed no effect,[119] and its use can trigger paroxysms of coughing. Hyperimmune serum (raised by immunization of adults with acellular pertussis vaccines) given intramuscularly reduced whooping significantly in infants treated in the first week of disease in a double-blind study in Sweden.[120] Pertussis immune globulin intravenous (P-IGIV), prepared from plasma of adults immunized with pertussis toxoid was evaluated in a prospective, placebo-controlled clinical trial in the US and Canada but was terminated prematurely because of expiration of P-IGIV lots. No benefit was noted in these studies,[121] and P-IGIV product is no longer available. Commercial IGIV is not indicated.

Several reports show that infants with pertussis who fail mechanical ventilation and are managed using extracorporeal membrane oxygenation have extremely high death rates (>80% in infants <6 weeks of age).[76,92,99] Several single cases and small series of young infants with extreme leukocytosis, respiratory insufficiency despite ventilator therapy, and pulmonary hypertension have been reported to survive after rapid leukoreduction by leukopheresis or exchange transfusion.[122–127] In a collaborative intensive care unit study of 127 cases, however, there was no apparent survival benefit of leukoreduction.[104] In a single case report, an infant with severe pulmonary hypertension treated with sildenafil and inhaled nitric oxide survived.[128]

Control Measures

Isolation

In addition to standard precautions, droplet precautions are recommended for at least 5 days after initiation of macrolide therapy. For infants who require longer hospitalization, isolation frequently is continued to avoid any possibility of spread, to reduce noxious stimuli, and to avoid the protective concern of other families.

Care of Household and Other Close Contacts

Postexposure prophylaxis (PEP) with a macrolide agent should be given promptly to all household contacts, other close contacts (such as those in childcare facilities), and closely exposed healthcare personnel (HCP) regardless of age, history of immunization, or symptoms.[111,112,129,130] PEP may not be necessary for all out-of-home exposures in adolescents. Choice of agent, dosage, and duration for PEP is the same as for treatment (see Table 162.4). Repeatedly, studies have shown high transmission rates and efficacy of macrolide chemoprophylaxis for maternal-neonatal exposure,[131] as well as in households[132,133] when prophylaxis is given before onset of a secondary case,[134] in residential facilities, and hospitals.[135] Visitation of coughing family members to the hospital must be controlled until they have taken a macrolide for 5 days. For outbreaks in childcare facilities and schools, all children, students, and staff who have cough illness compatible with pertussis should be excluded for 5 days after beginning therapy or for 21 days after onset of cough if not treated.

Immunization status of close contacts also should be considered. Children younger than 7 years who have received fewer than four doses of DTaP should be given further dose(s) to complete the recommended series; children who received a third dose 6 months or more before exposure, or a fourth dose 3 years or more before exposure, should be given a booster DTaP dose. Adolescents 10 years of age or older and adults who have not received Tdap, and DTaP-underimmunized children 7 through 10 years of age, should be given a single dose of Tdap.

Several outbreaks of pertussis have been described in a variety of inpatient and ambulatory healthcare settings, affecting HCP, with subsequent transmission from HCP to patients.[77,135–137] Guidance for management should be sought from infection preventionists and health departments.[138] Postexposure strategies are resource intensive and include contact identification, PEP, surveillance, and furlough of coughing HCP.[77,139] Pre-exposure vaccination and cough precautions should be stressed. Brisk response (by 2 weeks) of adults to Tdap also supports a role for vaccination of Tdap unvaccinated individuals in outbreak control.[140]

Even when *B. pertussis* infection is documented, the individual should complete the recommended immunization series: DTaP for those younger than 7 years, and Tdap for adolescents and adults.[22,27]

Prevention

Current Vaccines and Strategies

DTaP is given universally in the US in a 5-dose series in children 6 weeks through 6 years of age. In 2006, a single dose of Tdap was recommended universally for 11- or 12-year-olds, with catch-up for older adolescents[22,27]; for all HCP; for all adults younger than 65 years to replace one decennial dose of Td, and for wound prophylaxis. In 2010–2011, a single dose of Tdap was recommended for children 7 through 10 years of age who previously were not fully immunized with DTaP.[141,142] The CDC expanded Tdap recommendation to all adults 19 years and older (i.e., including >64 years of age) who previously did not receive Tdap. In 2011, one Tdap product (Boostrix) was FDA licensed for use in people 65 years of age and older; Boostrix is preferred over Adacel when available (see Chapter 6 and reference 29).

DTaP and Tdap vaccines available in the US are composed of varying amounts of PT, FHA, and pertactin; Sanofi Pasteur vaccines also contain *fim2* and *fim3*. Vaccine effectiveness for DTaP ranges from 75% to 90% immediately after the primary series.[143,144] Short-term effectiveness of adolescent Tdap observed in field studies is approximately 70%.[145] There is rapid waning of antibody and protection after the DTaP series and Tdap in people who never received DTP (see earlier sections “Epidemiology” and “Immunity”). Because of short duration of Tdap protection, routine boosting is not cost effective or recommended currently for the general population or for HCP. Active research facilitated by the primate model of pertussis seeks better understanding of infection and immunologic responses as well as optimized antigens, adjuvants, and toxoiding methods for novel vaccines.[146]

Many studies have shown that household contacts (currently siblings more commonly than parents) are sources for pertussis in neonates.[70,71,147,148] The American Academy of Pediatrics (AAP), the CDC, the American College of Obstetricians and Gynecologists, and many European countries recommend a cocoon strategy (immunization of women, families, and other contacts) to increase protection of young infants. In 2012, the CDC and the UK Department of Health recommended universal administration of Tdap during *each* pregnancy, optimally between 27 and 36 weeks (US, Tdap) or 28 and 38 weeks (UK, DTaP/IPV) of gestation, as the cornerstone of reduction of pertussis-related deaths.[149,150]

Uptake in the UK has been much higher than in the US. Safety data in an observational study of >20,000 vaccinated pregnant women in the UK[151] were reassuring, as was a small prospective placebo-controlled trial in the US.[152] Observational and case-control studies in England and Wales demonstrate approximately 90% effectiveness of vaccination during pregnancy in preventing pertussis in infants younger than 2 months.[153,154]

If not given during pregnancy, Tdap should be administered immediately postpartum to women who never received Tdap. Catch-up immunization should be performed for underimmunized siblings (DTaP for those <7 years of age and Tdap for those 7−10 years of age) and for previously Tdap unimmunized adolescents and adults of all ages.[141,142]

Pertussis vaccination in the neonatal period using DTaP has been studied and is associated with interference with responses to other infant vaccines.[155–158] Tdap immunization during pregnancy has not appeared to adversely affect subsequent infant or toddler responses to DTaP and other vaccines, although additional studies are in progress.[152,159] The standard DTaP series can be begun at 6 weeks of age. Studies from the CDC and Sweden showed protective effect against pertussis death in infants 42 days or older who had received 1 dose or more of vaccine (aOR, 0.28; 95% CI, 0.11−0.74).[160,161]

Rates of local and systemic adverse reactions after vaccination are lower following DTaP than DTP vaccine, as are hypotonic-hyporesponsive episodes and febrile seizures. In a study of 14 children who developed encephalopathy with seizure onset within 72 hours of whole cell DTP vaccination, 11 patients were found to have genetic epileptic encephalopathy due to mutations in a neuronal sodium channel gene, *SCN1A*,[162] with vaccine-associated fever likely unmasking the condition. Rates of local reactions are increased with the fourth and fifth doses of DTaP. Tdap vaccination does not appear to be more reactive after all-acellular primary series.[163] Tdap should be administered when indicated regardless of interval since receipt of diphtheria- or tetanus-toxoid containing vaccines.[141–142] Local and systemic events following administration of Tdap are similar to those following Td,[163–165] with no increase with a short interval (1 month to 2 years) between receipt of DT- or Td-containing vaccines and Tdap.[166–170]

Extensive limb swelling (ELS) of the injected extremity has been reported in 2% to 6% of children receiving the fourth or fifth doses of DTaP.[171–174] ELS is self-limited; the pathogenesis is not fully understood, and the reaction is not consistently related to diphtheria or tetanus content, pertussis proteins, or aluminum content of vaccines.[175,176] ELS has been reported almost as frequently after Td and hepatitis B vaccinations in adolescents.[168] In a study of 20 children who had ELS after dose 4 of DTaP, 5 children had ELS and 7 had swelling >5 cm after dose 5, but all events were well tolerated and resolved rapidly.[177] ELS is not a contraindication to further recommended doses of DTaP, or to Tdap.[22,27,112]

New Vaccine Approaches

The increase in pertussis disease in developed countries such as Europe and the US suggests the need for new vaccine approaches. The findings from baboon studies also suggest that immunization with acellular vaccine does not prevent infection and transmission. New vaccine strategies being evaluated include development of live, attenuated *B. pertussis* vaccine[178]; reintroducing less reactogenic whole cell vaccines for at least the first vaccine dose; use of adjuvants in combination with the acellular vaccines; and addition of other pertussis antigens to vaccines used currently.[179] Human challenge models, like the baboon model, could be employed to evaluate transmission as well. Finally, better understanding of the role of Th17 in immunity to pertussis should be pursued.[179]

Campylobacter jejuni and *Campylobacter coli*

Jumi Yi, Evan J. Anderson

Campylobacter spp. are one of the most common causes of culture-proven bacterial gastroenteritis in developed and developing countries.[1–3] In the United States, the annual incidence is about 13.5 per 100,000 persons and is highest in children younger than 5 years.[4–6] Although diarrhea is the most common clinical manifestation, *Campylobacter* infections can be asymptomatic or can result in bacteremia, localized extraintestinal findings, or inflammatory and autoimmune manifestations such as reactive arthritis and Guillain-Barré syndrome (GBS).

Description of the Pathogen

The genus *Campylobacter* (from the Greek and Latin meaning "curved rod") comprises gram-negative, mostly microaerophilic bacteria. These curved, spiral, or S-shaped bacteria are 0.2 to 0.5 µm wide and 1 to 5 µm long and possess rapid and darting motility in corkscrew fashion by means of a single, unsheathed flagellum in one (monotrichous) or both (amphitrichous) ends. Campylobacters are commensal organisms living in the gastrointestinal tract of birds and mammals. *Campylobacter* genomes are relatively small (approximately 1600–1900 genes). The complete genomes of several *Campylobacter* spp. have been sequenced and include a variety of genes involved in biosynthesis and modification of carbohydrate surface structures that may be involved in antigenic variation and molecular mimicry.[7–10]

As of 2014, the genus *Campylobacter* included 26 species, two provisional species, and nine subspecies.[4,11] About one half of these are known human pathogens, although human illness is mostly due to *C. jejuni* and *C. coli* and less frequently to *C. upsaliensis, C. lari,* and *C. fetus* (Table 163.1; see also Chapter 164). *C. jejuni* is reported in about 90% of diarrheal illnesses caused by *Campylobacter*.[4] *C. coli* is not common in the United States but may cause up to 25% of *Campylobacter*-related illness in certain regions.[1] In addition, *C. jejuni* can lead to autoimmune manifestations such as GBS.[1] *C. jejuni* and *C. coli* have similar epidemiology and clinical features, and belong to the same cluster phylogenetically.

TABLE 163.1

Taxonomy, Clinical Syndromes, and Common Sources of *Campylobacteria* That Are Pathogenic to Humans

Organism	Associated Illness	Reservoir
CAMPYLOBACTER SPECIES		
C. jejuni subsp. *jejuni*	Diarrhea, bacteremia, meningitis, Guillain-Barré syndrome, reactive arthritis	Poultry, cattle, dog, cat, sheep, monkey
C. jejuni subsp. *doylei*	Diarrhea, bacteremia	Pig
C. coli	Diarrhea, bacteremia, meningitis	Pig, poultry
C. upsaliensis	Diarrhea, bacteremia	Dog, cat
C. lari	Diarrhea, bacteremia	Wild birds, poultry, dogs, cats
C. fetus subsp. *fetus*	Bacteremia, endocarditis, abscess, meningitis	Cattle, sheep, reptiles
C. hyointestinalis	Diarrhea	Pig, cattle, hamster
C. concisus	Periodontal diseases, diarrhea, abscesses	Humans, domestic pets
C. sputorum subsp. *sputorum*	Abscesses, diarrhea	Cattle, pigs
C. curvus	Alveolar abscess, diarrhea	Human oral cavity
C. rectus	Periodontitis, abscesses	Human oral cavity

Epidemiology

Enteric *Campylobacter* infections are common worldwide. *C. jejuni* is the most common species of *Campylobacter* isolated from patients with diarrhea in both developed and developing countries.[1,3,12,13] In developed countries, illness occurs across all age groups but predominates in infants and young children and young adults.[1,2,14] *Campylobacter* can cause outbreaks.[1,2,6] *C. jejuni* rate doubles in the summertime, which might be explained by poultry contamination during the hotter months of the year and increased consumption of more barbecued and undercooked poultry.[15] In the US, *Campylobacter* is estimated to cause about 845,000 illnesses, 8500 hospitalizations, and 76 deaths annually.[16] Outbreaks of *Campylobacter* occur typically in the setting of contaminated poultry products, dairy, or water exposure.[1,16] Preliminary data from the Foodborne Diseases Active Surveillance Network (FoodNet) showed that *Campylobacter* infection rates increased by 13% in 2014 (13.5 per 100,000) compared with 2006–2008.[6] In comparison, rates of Shiga toxin−producing *Escherichia coli* O157 and *Yersinia* decreased, and *Listeria* and *Salmonella* exhibited no change.[6] *Campylobacter* fluctuates with *Salmonella* as the most common bacterial cause of foodborne illness in the US and was second to *Salmonella* in 2014.[6] *Campylobacter* also was the leading cause of travel-associated diarrhea in the US during 2004–2009, accounting for 42% (3445/8270) of cases, followed by *Salmonella* (32%) and *Shigella* (13%).[17]

In resource-limited settings, *Campylobacter* is detected year-round and is the most common bacteria isolated from infants with diarrhea due to continuous exposure to contaminated water and food.[13] Seasonality is usually less pronounced or absent, asymptomatic infections are common, and diarrhea typically occurs in children but not adults.[3] However, epidemiologic data are lacking in these settings owing to poor surveillance and insensitive methods of detection.[3] A multinational population-based surveillance study of more than 9000 children younger than 60 months with moderate to severe diarrhea (and controls) in resource-limited settings detected *C. jejuni* as a significant pathogen in children younger than 1 year in Bangladesh and Pakistan and in children 2 to 5 years of age in Pakistan and India.[18] *Campylobacter* was not associated with significant burden of diarrhea in the African countries in this study (Mali, Kenya, The Gambia, and Mozambique).[18] Additional data are needed to better understand the burden of *Campylobacter* in resource-limited settings.

Enteric *Campylobacter* infection has several well-defined modes of transmission. The most important is the ingestion of contaminated food such as undercooked poultry and meat and unpasteurized milk.[2,6,19–21] Ingestion of contaminated water and direct contact with animals, including pets and animals on farms and in slaughterhouses, has also been documented.[21–24] Person-to-person transmission is rare but does occur in childcare centers and in families,[25,26] as does perinatal transmission through contact with a contaminated birth canal[27] and through sexual contact among men who have sex with men.[28–30]

Pathogenesis

In susceptible individuals, as few as 360 colony-forming units are required to induce diarrhea.[31] Although *C. jejuni* is killed by hydrochloric acid at pH 2.3, it can survive in milk or water for several weeks.[32] The mechanisms by which *C. jejuni* induces disease are not well understood, but the process involves bacterial virulence and colonization factors involved in surviving passage through the stomach and small intestine, and subsequent colonization and growth in the distal ileum and colon.[32–34] Several proposed mechanisms of virulence and survival are listed in Table 163.2.

TABLE 163.2

Proposed *Campylobacter* Virulence and Survival Factors

Virulence/Survival Factor	Target/Effect
Flagella/chemotaxis	Navigation to favorable colonization sites (e.g., mucus-filled crypts of chick ceca) Facilitate invasion of host cell
Adherence	Binds to fibronectin on gastrointestinal epithelial cells Induces internalization of organisms
Cytolethal distending toxin	Blocks host cell progression to mitosis Causes cell death
Lipo-oligosaccharide	Facilitates colonization Enhances immune evasion Affects molecular mimicry resulting in immune-mediated manifestations such as Guillain-Barré syndrome
Iron uptake	Enhances survival and colonization in poultry
Multidrug efflux pump	Permits drug, bile, and heavy metal resistance

Stress response	Causes downregulation of cellular responses that favor growth in times of limited amino acid availability Increases amino acid synthesis that enhances survival Has high frequency of intragenomic recombination leading to ability to survive in unfavorable conditions Expresses antioxidants to resist host immune response Enters a viable but nonculturable state in response to reduced pH or during starvation

Three general stages during *Campylobacter* infection have been postulated to lead to different clinical syndromes: (1) colonization and adherence to the epithelium of the distal ileum and colon may result in noninflammatory diarrhea through unknown mechanisms; (2) invasion and proliferation within the intestinal epithelium causes cell damage and an inflammatory response clinically manifest as dysentery with fecal leukocytes; and (3) translocation across the intestinal epithelium with spread to mesenteric lymph nodes causes mesenteric adenitis, and also causes spread to extraintestinal sites (e.g., bacteremia, meningitis).[1,32,35]

Immunity

Immunity to *C. jejuni* develops after one or more infections.[36–39] Children living in endemic areas have a progressive decrease in the illness-to-infection ratio with increasing age.[40] Cohort studies also demonstrate that *Campylobacter* diarrhea occurring in young children protects against subsequent reinfections; however, no protection occurs after asymptomatic infection.[40] Serum antibodies to specific antigens of *Campylobacter* increase after natural infection.[36,38,41] Experimental challenge studies in volunteers show that rechallenge with the same strain of *C. jejuni* is associated with protection at 1–2 months after the initial challenge and partial protection at 1 year after the initial challenge, resulting in milder illness.[39,42] Immunocompromised patients can develop prolonged, severe, and recurrent *C. jejuni* infections and fail to respond to therapy or mount a humoral response.[43–45]

A rapid and intense serum response involving both monomeric and polymeric immunoglobulin A (IgA) occurs in the first week, reaches a peak after the second week, and declines to low levels within 30 days after the onset of symptoms.[46] A local secretory IgA response also occurs after *Campylobacter* enteritis.[46] Patients infected with *C. jejuni* O:19, the serotype most frequently associated with

GBS, had a significantly higher IgA antibody response than did patients infected with other serotypes.[38] Isotype-specific IgG and IgM antibodies peak on days 15 to 21 and decrease to low levels within 3 months after onset of symptoms.[36,38] In persons who are chronically exposed in hyperendemic areas, serum-specific IgA antibodies increase progressively through life.[36] *Campylobacter* antibody levels in populations in developed compared with developing countries are significantly lower.[47] Studies in breastfed Mexican children have demonstrated protection against *Campylobacter* diarrhea conferred by specific secretory IgA antibodies present in human milk.[41,48] Human and mouse experimental infections also suggest that cell-mediated immune responses are important and correlate with protection against *Campylobacter* enteric infections.[39,49]

Clinical Manifestations

Campylobacter infections produce clinical manifestations that are particular to the species involved as well as characteristics of the host, such as age, immunosuppression, and underlying chronic and debilitating illnesses (see Table 163.1). The most common clinical finding is enteritis, of which >90% of cases are caused by *C. jejuni*.[2–4] Bloodstream infections (BSIs), extraintestinal infections, and perinatal infections are rare and are caused by other *Campylobacter* spp.

Enteritis

Campylobacter enteritis in children typically is mild but also can manifest as inflammatory diarrhea.[1,4,40,50] Symptoms usually start 24–72 hours after ingestion, and the peak of symptoms typically lasts 24 to 48 hours.[1]

Substantial differences in the clinical characteristics of diarrhea occur in children in developed and developing countries. Inflammatory diarrhea is more common in developed countries, whereas secretory diarrhea seems to prevail in resource-limited settings and in younger children. Vomiting and dehydration may also occur.[3,4,13,40] In general, episodes are mild and self-limited; 60% to 70% subside within 1 week, 20% to 30% subside in 2 weeks, and

5% to 10% persist for several weeks. Relapses can occur. In one third to one half of patients, the onset of diarrhea is preceded by intense abdominal pain, malaise, myalgia, and headache.[50] Pain generally lasts a week and is periumbilical and cramping and when present can be severe in 20% of patients, sometimes mimicking appendicitis.[51] When laparotomy is performed, mesenteric lymphadenitis or signs of ileocolitis are found. In patients who have undergone proctoscopy or colonoscopy because of a protracted course of illness, 50% show evidence of mucosal edema, congestion, friability, and granularity. The spectrum of histologic changes ranges from minimal edema with acute and chronic inflammatory cells without vascular congestion, to moderate inflammation with cryptitis and crypt abscess formation.[52]

The clinical features of inflammatory diarrhea are indistinguishable from those caused by *Shigella* and are characterized by generalized malaise, fever, abdominal cramps, tenesmus, and bloody stools. Severe cases, which are rare, can occur in adolescents and young adults and can be mistaken for ulcerative colitis, Crohn disease, or pseudomembranous colitis; occasionally, disease progresses to toxic megacolon, massive bleeding, or colonic perforation.[53–55] In neonates, blood streaking of formed stool has been associated with *C. jejuni*.[56,57] Abdominal examination can reveal tenderness to deep palpation, especially in the right lower quadrant. Splenomegaly has been reported rarely.

If specific treatment is not given, fecal shedding of *Campylobacter* persists for a median of 2 to 3 weeks, with a range of 3 days to several months.[40,56,58] Younger children tend to shed the organism for longer periods.[59] Severe, persistent, and recurrent *C. jejuni* infections have been reported in patients with immunodeficiencies, including congenital or acquired hypogammaglobulinemia and AIDS.[40,43–45]

Bloodstream Infection

BSI due to *C. jejuni* is relatively rare and occurs in <1% of children with enteritis and mostly in malnourished children, patients with chronic debilitating illnesses or immunocompromising conditions, and elderly patients.[40,60] *C. jejuni* or *C. coli* organisms account for 60% to 90% of blood isolates, followed by *C. fetus* in 8% to 15%. BSI can be transient and asymptomatic in normal hosts but severe in hosts who are immunosuppressed, with mortality of 10% to 15%.[43,61–63] Most episodes of BSI occur in patients with diarrhea.

Three clinical manifestations of BSI are described: (1) cryptogenic BSI, which occurs as an isolated event that is self-limited or readily responds to antibiotics; (2) secondary BSI associated with focal infections such as meningitis, pneumonia, endocarditis, and thrombophlebitis; and (3) chronic BSI with relapses that can persist for several months (mostly in immunosuppressed patients).

Localized Extraintestinal Infections

A localized infection can be the first manifestation of *C. jejuni* infection or can occur after or simultaneously with BSI. Extraintestinal infections caused by *C. jejuni* include cholecystitis, urinary tract infection, pancreatitis, septic arthritis, and meningitis.[64–69] These manifestations are uncommon and generally occur in patients who are immunosuppressed or at the extremes of age.[70]

Perinatal Infections

Perinatal infections rarely have been associated with *C. jejuni*. Three clinical manifestations of perinatal infection have been described: abortion and stillbirth, premature labor, and neonatal septicemia and meningitis.[68,69,71–73] Symptomatic gastroenteritis and bloody diarrhea attributable to *C. jejuni* are reported in neonates, with the mother (who can be symptomatic or asymptomatic at the time of delivery) usually being the source.[56] In general, perinatal infections caused by *C. jejuni* are less severe than those caused by *C. fetus*.

Immune-Mediated Complications

Immune-mediated complications such as GBS, reactive arthritis (formerly Reiter syndrome), erythema nodosum, and inflammatory bowel disease occur occasionally after *C. jejuni* diarrhea.[67,74–80] *Campylobacter* is the single most common cause of GBS, and annual rates of campylobacteriosis correlate directly with rates of GBS.[81,82] The risk for GBS within 2 months of a symptomatic *Campylobacter* infection is 100-fold that of the general population, and about 30%

to 40% of patients with GBS are infected with *Campylobacter* in the preceding 2 weeks. People 60 years and older are at highest risk for GBS (248 cases per 100,000 *Campylobacter* infections), whereas GBS is rare in children.[83,84] The pathogenesis of *Campylobacter*-induced GBS is thought to be cross-reactivity between antibodies produced against *C. jejuni* lipo-oligosaccharide and human ganglioside (e.g., GM_1) resulting in nerve damage. T-lymphocyte response to lipo-oligosaccharide also is thought to contribute to GBS.[1] Patients with *C. jejuni*–associated GBS are more likely than other patients with GBS to have neurophysiologic features of axonal neuropathy, antibodies to ganglioside GM_1, pure motor GBS, and poor outcome.[74,75,85] Cranial nerve involvement occurs in one third of cases, and recovery is complete in most patients.[85] Miller Fisher syndrome, a polyneuritis variant characterized by ophthalmoplegia, areflexia, ataxia, and high levels of IgG antibodies to ganglioside GQ_{1b}, also has been associated with preceding *Campylobacter* infection.[86–89] A third variant is acute motor axonal neuropathy, or Chinese paralytic syndrome, which is characterized by an explosive onset with rapid progression to tetraplegia and respiratory failure.[90–93] The illness is due to a reversible lesion of the motor nerve terminal or anterior horn cell. Epidemics of acute motor axonal neuropathy have occurred in northern China for >20 years, taking place in the summer and fall in rural areas and involving mainly children.[92]

Reactive arthritis can be associated with *Campylobacter* enteritis as well as with *Salmonella, Shigella,* and *Yersinia* enteritis.[67,78,79] It is relatively more common in young male adults. Arthritis begins 3 to 40 days (mean, 11 days) after the onset of diarrhea, usually is oligoarticular and asymmetric (affecting mainly the knees), is of short duration (range, 1–21 days), and has no sequelae. Arthralgia is reported in up to 20% of infected patients. Synovial fluid is sterile, and fever and leukocytosis are absent, but the sedimentation rate is elevated. The histocompatibility antigen HLA-B27 has been associated with more severe or prolonged illness in some studies.[94]

Some studies also suggest an association between *Campylobacter* infection and postinfectious irritable bowel syndrome, especially in those having diarrhea for >7 days.[95] Other potential host predisposing factors for postinfectious irritable bowel syndrome include younger age, female sex, prior anxiety or depression, and fever and weight loss during the acute enteric illness.[96,97]

Diagnosis

Several methods of *Campylobacter* diagnosis are available clinically. Isolation from stool culture is the gold standard in enteritis. Several methods are available for isolation of campylobacters from stool, food, and environmental samples that take advantage of their innate antibiotic resistance, slender morphology, and tolerance to high temperatures.[98–100] Use of blood or charcoal agar containing selective antibiotics that suppress the growth of the normal human colonic microflora permit growth as nonpigmented colonies that have oxidase activity.[101] Many *Campylobacter* spp., other than *C. jejuni* and *C. coli,* can be susceptible to the selective antibiotics. To circumvent this issue, some have used cellulose membranes filtration enrichment that traps most colonic organisms but allows slender campylobacters to pass through.[102] All species associated with human diseases grow better in a microaerophilic atmosphere containing 5% to 10% oxygen, and 3% to 5% CO_2, and can grow at 37°C. *C. jejuni* and *C. coli* grow best at 42°C, likely an adaptation for inhabitation of the intestine of birds, the natural hosts of thermophilic campylobacters; normal avian body temperature is 38°C to 42°C.

Biochemical techniques then can be used to identify the genus and species. Molecular techniques of matrix-assisted laser desorption ionization−time of flight (MALDI-TOF) spectrophotometry and multiplex polymerase chain reaction (PCR) also can be used to identify *Campylobacter*.[103–105] Multiplex PCR is anticipated to change diagnostics over the next several years. PCR is highly sensitive, detecting *C. jejuni* and *C. coli*, but is not species specific. PCR can detect asymptomatic shedding (the duration of which has not been established in children); results should be interpreted in the context of clinical findings.[105] Sensitivity of rapid enzyme immunoassay antigen testing of stool may approach that of culture, but false-positive results can occur (possibly related to blood) that can misdirect management.[106,107] Isolation of an organism from culture can be characterized further (e.g., subtyping) and is important for public health purposes.[108]

Campylobacteriosis is a nationally notifiable disease through the

Centers for Disease Control and Prevention (CDC) National Notifiable Diseases Surveillance System and should be reported to the appropriate state health department. Although culture is the preferred method of diagnosis, the National Notifiable Diseases Surveillance System recognizes that this method of detection is not consistently used in all clinical laboratories. Information can be found at http://wwwn.cdc.gov/nndss/conditions/campylobacteriosis.

Treatment

Rehydration and correction of electrolyte abnormalities are the mainstay of treatment for enteritis. Need for antibiotic treatment is debated but should be considered for *C. jejuni*–infected patients who have bloody or severe diarrhea, fever, or worsening of symptoms and for immunosuppressed patients. Antimotility agents have been associated with prolongation of symptoms and fatalities and should not be used.[109,110]

Campylobacter spp. often are resistant to penicillin, ampicillin, and cephalosporins. Most strains of *C. jejuni* and *C. coli* are susceptible to erythromycin, azithromycin, gentamicin, carbapenems, and chloramphenicol.[111–114] When antibiotic therapy is indicated for gastroenteritis, erythromycin or azithromycin is the drug of choice.[115,116] Erythromycin shows little propensity to select for plasmid-mediated resistance, which mainly is selected by point mutations. Although erythromycin resistance currently is low, it is an emerging health concern, especially in countries that use erythromycin in food-producing animals.[117,118] *C. coli* harbors higher rates of erythromycin resistance than *C. jejuni*.[6,119] Macrolide-resistant isolates tend to be multidrug resistant.[120,121] Studies have shown no clinical benefit of erythromycin therapy over placebo if given late in the course of disease.[111,115,122] If antibiotic therapy is initiated within the first 4 days of illness, fecal excretion might be reduced; results are conflicting regarding resolution of symptoms.[118,123,124]

There has been an increase in fluoroquinolone resistance in the past decades.[125,126] Rise in resistance coincides with the licensure of fluoroquinolones for use in poultry and veterinary medicine.[126,127] Basic mechanisms of resistance are outlined in Table 163.3. The most widely studied mechanism of resistance is the cmeABC efflux pump, which results in resistance to multiple drugs including fluoroquinolones and macrolides.[128,129] In countries such as Spain, Thailand, Taiwan, and Hong Kong, fluoroquinolone resistance is ≥80%.[119,130] In one study from China, the rate of fluoroquinolone resistance in *C. jejuni* increased from 44% in 1994–1998 to 98% in 2005–2010.[131]

TABLE 163.3

Mechanisms of Resistance

Mechanisms of Resistance	**Examples**	**Antibiotic Class Affected**
Modification of antibiotic target	DNA gyrase mutation	Fluoroquinolone
	23S rRNA mutation	Macrolide
	TetO binding to target ribosomal A site	Tetracycline
Efflux pump	cmeABC (multidrug efflux pump)	Macrolide, fluoroquinolone, β-lactam
Inability of antibiotic to reach target	Expression of major outer membrane protein leading to decreased membrane permeability	β-lactam antibiotics, macrolide
Modification or inactivation of antibiotic	β-lactamase	β-lactam antibiotics
	Aminoglycoside-modifying enzymes	Aminoglycosides

The CDC National Antimicrobial Resistance Monitoring System monitors antibiotic resistance for select enteric bacteria (http://www.cdc.gov/narms/reports/index.html). As of 2013, ciprofloxacin resistance in *C. jejuni* in the US remained stable at 22%, but macrolide resistance doubled in *C. coli* from 9% in 2012 to 18% in 2013.[132]

Prevention

Pasteurization and chlorination of water kill *C. jejuni*, but organisms survive in milk or other foods kept at 4°C. Because campylobacters have relatively high temperature requirements, they tend not to multiply in foods (in contrast to *Salmonella*), and therefore most cases are sporadic rather than occurring in large outbreaks. Milkborne outbreaks have been reported as a result of the consumption of unpasteurized or ineffectively pasteurized milk,[133,134] and a few waterborne outbreaks have been described.[135,136] About 50% to 80% of all human campylobacteriosis is related to chickens.[137] Strategies to decrease *Campylobacter* infections in humans are being explored and include removing *Campylobacter* from colonized chickens, reducing environmental exposures, and increasing the resistance of chickens to *Campylobacter*.[6,137]

Key Points

Campylobacter jejuni and *Campylobacter coli*

Epidemiology

- A major cause of bacterial gastroenteritis worldwide
- Highest incidence occurs in infants and young children.
- Well-defined modes of transmission are undercooked poultry, undercooked meat, and unpasteurized milk.

Clinical Features

- Generally a mild illness, but inflammatory diarrhea and hospitalization can occur; extraintestinal infections and death are rare.
- Most common cause of Guillain–Barré syndrome
- Most perinatal infections are caused by *C. fetus*.

Diagnosis

- Stool samples cultured on selective media are the gold standard.

Treatment and Prevention

- Rehydration and correction of electrolyte abnormalities are the mainstays of therapy.
- Consider antimicrobial therapy in patients with bloody or severe diarrhea, fever, worsening of symptoms, or patients who are immunosuppressed.
- Drug of choice for enteritis is azithromycin or erythromycin.

- Antibiotic therapy for enteritis may be beneficial when given within the first 4 days of illness.
- Fluoroquinolone resistance occurs in about 22% of US isolates but is higher in some other countries.
- Antimotility agents are contraindicated.
- Pasteurization and chlorination of water kill *C. jejuni*.

Other *Campylobacter* Species

Bethany K. Sederdahl, Evan J. Anderson

The genus *Campylobacter* includes approximately 26 species and 9 subspecies.[1] Of the *Campylobacter* species that are associated with human disease, *C. jejuni* is the prototype for enteric infections, and *C. fetus* is the prototype for extraintestinal infections. *Campylobacter* spp. other than *C. jejuni* and *C. coli* isolated from stool are estimated to comprise 3% of *Campylobacter* isolates.[2] Refinement of microbiologic techniques for isolation of *Campylobacter* spp. and use of molecular assays have expanded our knowledge about the diversity of *Campylobacter* spp. and the spectrum of human infections associated with these organisms.[3–6] However, *Campylobacter* spp. other than *C. jejuni* and *C. coli* may be significantly underdiagnosed as causes of gastrointestinal tract disease because selective *Campylobacter* media and incubation conditions may inhibit their growth, and similarities between their biochemical characteristics may make species identification difficult.[7]

Phylogenetic trees have been established for *Campylobacter* on the basis of 16S ribosomal DNA sequences. These trees contain three distinct clades or species groups (Table 164.1).[8] The first clade includes *C. fetus* and *C. hyointestinalis,* which are generally associated with disease in farm animals. The second clade includes *C. coli, C. jejuni, C. lari,* and *C. upsaliensis,* which are associated with gastroenteritis in humans. The third includes *C. curvus, C. concisus,* *C. gracilis, C. rectus, C. showae,* and *C. sputorum,* which are associated with the periodontal cavity of humans and animals. *C. jejuni* and *C. coli* are described in Chapter 163.

TABLE 164.1

Location of and Disease Associated With *Campylobacter* Species

Association or Disease	*Campylobacter* Species
Disease in farm animals	*C. fetus*[a]
	C. hyointestinalis[a]
Gastroenteritis and rarely bacteremia	*C. coli*[a]
	C. jejuni[a]
	C. helveticus
	C. lari[a]
	C. upsaliensis[a]
Periodontal cavities of humans and animals	*C. curvus*
	C. concisus
	C. gracilis
	C. rectus
	C. showae
	C. sputorum

[a] Clearly associated with human disease.

Campylobacter fetus

In 1913, McFadyean and Stockman found a *Vibrio*-like organism in aborted ovine fetuses and proposed the name *Vibrio fetus ovis*.[9] The same organism later was implicated as a cause of abortion and infertility in other domestic animals, and the name was shortened to *V. fetus*.[10] A second type of infection in cattle and sheep, causing sporadic abortion but not infertility, was recognized; the causal agent was named *V. fetus* subsp. *venerealis*.[11] In 1947, Vincent and colleagues reported the first human infection by *C. fetus* in a pregnant woman with bloodstream infection (BSI) who aborted at 6 months of gestation.[12] Currently, three subspecies of *C. fetus* have been recognized: *C. fetus* subsp. *fetus*, *C. fetus* subsp. *venerealis*, and *C. fetus* subsp. *testudinum*.[1,13] *C. fetus* subsp. *fetus* and *venerealis* cause infection of the genitourinary tract of sheep and cattle. *C. fetus* subsp. *testudinum* is newly identified organism that has been associated with bacteremia and diarrhea in adult men, most of whom had reptile exposure.[13] It appears to be an opportunistic pathogen, affecting immunocompromised or elderly individuals.

Only *C. fetus* subsp. *fetus* and *testudinum* have been identified as causing disease in humans.

Microbiology and Epidemiology

C. fetus subsp. *fetus* are curved, gram-negative, microaerophilic bacteria that are oxidase, catalase, and nitrate positive; they grow at 25°C and 37°C, but not at 42°C. It is estimated that at least 20% of *C. fetus* infections are undetected since isolation is typically performed at 42°C.[14] A paracrystalline protein structure composed of S-layer proteins surrounding the bacterial outer membrane is a unique virulence factor of *C. fetus* and *C. rectus*. This structure is implicated in invasion, resistance to phagocytosis and complement-mediated killing, and immune evasion by antigenic variation.[15–19]

Although *C. fetus* accounts for 0.3% to 3.9% of all *Campylobacter* isolates, it is identified in 19% to 53% of *Campylobacter* bacteremia.[20–24] A source of *C. fetus* infection seldom is identified, although cases have been reported with cattle or sheep exposure, after ingestion of raw milk or contaminated food or water, by sexual and transplacental transmission, and in neonates after vaginal delivery.[25–30]

In adults, nearly 75% of reported *C. fetus* infections are in men, and 62% to 74% of systemic cases occur in patients with underlying conditions such as alcohol abuse, liver disease, diabetes mellitus, human immunodeficiency virus (HIV) infection, or malignancies.[22,23,31–36] There also is an increased risk for infection among healthy elderly individuals and pregnant women.[14,37] Although uncommon, *C. fetus* infection during pregnancy can result in birth complications and systemic infection of the neonate.[30,38] *C. fetus* infections in children are usually confined to the neonatal period in association with maternal infection, but case reports of infection in children with underlying disease describe *C. fetus* septicemia, hepatitis, and pericarditis.[30,39–41]

Clinical Manifestations and Management

In humans, *C. fetus* infection generally causes a systemic illness manifesting as fever and can be associated with translocation of the organism through a relatively intact intestinal mucosa to the reticuloendothelial system and the bloodstream.[24] BSI is the most common manifestation of *C. fetus* infection; this organism appears to have a predilection for vascular endothelium, with manifestations such as thrombophlebitis, pericarditis, mycotic aneurysms, and endocarditis.[41–46] Patients with BSI due to *C. fetus* should be evaluated for localized vascular infection. Confusion and lethargy are common, although focal neurologic signs are unusual except when meningitis or cerebral abscesses are present. The following three clinical presentations of BSI have been described: (1) cryptogenic BSI occurring as an isolated event that is self-limited or readily responds to antimicrobial therapy; (2) secondary BSI, the most common presentation, associated with focal infections such as meningitis, pneumonia, endocarditis, and thrombophlebitis; and (3) chronic BSI with relapses that can persist for several months, occurring mostly in immunosuppressed patients.

A focal lesion can be the first manifestation of *C. fetus* infection or can occur after or simultaneously with BSI. Meningitis, cholecystitis, pancreatitis, cellulitis, urinary tract infection, lung and gluteal abscesses, pericarditis, endocarditis, thrombophlebitis, septic arthritis, and salpingitis have been reported.[47–54]

Mortality from *C. fetus* BSI has been estimated at 14%, with higher rates among patients who have secondary BSI with a distant focal infection.[36] Infections with *C. fetus* usually are systemic and therefore require parenteral antibiotic therapy. *C. fetus* organisms often are susceptible to ampicillin and gentamicin, but imipenem or meropenem is preferred for treatment pending results of in vitro susceptibility tests.[30,55,56] Duration of therapy depends on the site of infection.

Three clinical manifestations of perinatal infection have been described: abortion and stillbirth, premature labor, and neonatal septicemia and meningitis.[38,57–62] The pathology of perinatal *C. fetus* infection consists of placental necrosis, and widespread endothelial proliferation, intravascular fibrin deposition, perivascular inflammation, and hemorrhagic necrosis in the brain of the neonate.[63] An infected woman can harbor *C. fetus* with or without symptoms, having recurrent abortions or premature deliveries as a result.[29,38,62,64–68] In cases of neonatal septicemia and meningitis, *C. fetus* has been isolated from the maternal cervix or vagina.[47,62,68] Cervical cultures remained positive in women who had recurrent abortions and whose husbands had high antibody titers to the organism.[69] In general, perinatal infections caused by *C. fetus* are more severe than those caused by *C. jejuni*.[38]

Campylobacter upsaliensis

Microbiology

A species of thermotolerant, catalase-negative or weakly catalase-positive, cephalothin-susceptible *Campylobacter* was isolated from dogs with diarrhea in 1982.[70] DNA hybridization and phylogenetic studies with comparison of the 16S rRNA sequence demonstrated that this organism belongs to a new species, *C. upsaliensis*, named after the Swedish city in which it was first isolated.[71,72] *C. upsaliensis* now is considered a relatively common enteric pathogen of humans and can cause BSI in malnourished children and immunocompromised adults.[73–77]

C. upsaliensis can be differentiated from other *Campylobacter* species on the basis of several phenotypic characteristics.[72] Most strains are thermotolerant, which means that they grow well at 42°C, but not at 25°C. *C. upsaliensis* is weakly positive or negative for catalase production and does not produce hydrogen sulfide in triple sugar medium or hydrolyze hippurate. A high proportion of isolates possess multiple plasmids. All strains are susceptible to cephalothin and nalidixic acid. Because *C. upsaliensis* is susceptible to the antimicrobial agents used in *Campylobacter*-selective media, it is not detected in cultures using these media.[73]

Epidemiology, Clinical Manifestations, and Treatment

C. upsaliensis is underidentified in routine clinical laboratories, making the true prevalence of infection with this pathogen difficult to estimate.[78,79] *C. upsaliensis* is isolated more frequently from populations with poor sanitation and overcrowded conditions and frequently is isolated from dogs and cats with or without symptoms of infection.[78,80,81] Infections in humans sometimes are associated with close contact with infected dogs.[80,82–85] *C. upsaliensis* detection in dogs increases in the summer and fall, and *C. upsaliensis* is isolated more commonly in humans from May through November.[74,86,87] *C. upsaliensis* is reported as a gastrointestinal pathogen in children more often than adults.[74,88,89] Diarrhea of short duration is the most common clinical presentation; 25% of patients have gross or occult blood in stools, 20% have fecal leukocytes, and vomiting occurs occasionally, but the disease appears to be milder than that caused by *C. jejuni*.[74,87] In South Africa, testing for *Campylobacter* in stool from children with diarrhea identified *C. upsaliensis* in 24% of samples.[89] An outbreak of *C. upsaliensis* in childcare centers in Brussels described chronic or relapsing diarrhea that was likely related to fecal-oral transmission.[88] Serum antibodies to *C. upsaliensis* were found in most children with *C. upsaliensis*, indicating that the organism is not commensal.[88] In immunocompromised or malnourished children with diarrhea, the infection can progress to septicemia.[75–77,90] *C. upsaliensis* infection has been associated with abortion, and BSI was described in a patient with ruptured ectopic pregnancy.[91]

Experience with antimicrobial treatment of *C. upsaliensis* is limited. Resistance to streptomycin, vancomycin, methicillin, trimethoprim, and piperacillin has been observed, but isolates have been found to be susceptible to gentamicin, azithromycin, erythromycin, meropenem, cephalosporins, fluoroquinolones, tetracycline, and aminoglycosides.[72,86,92–95] Diarrhea generally can be treated with macrolide, but no controlled trials have been conducted, and in some studies up to 13% to 15% of *C. upsaliensis* strains are resistant to macrolides in vitro.[93]

Campylobacter lari

In the early 1980s, Skirrow and Benjamin isolated nalidixic acid –resistant, thermophilic campylobacters in seagulls and in feces of domestic animals, seals, and ducks.[96] Although *C. lari* has been isolated in up to 10% of cloacal swabs from chickens, transmission to humans is rare. *C. lari* accounts for 1% of all diarrhea-associated *Campylobacter* isolates.[97] *C. lari* BSI has been described in immunocompromised patients and neonates.[98–100] An outbreak of diarrhea occurred among construction workers who drank water contaminated by surface water from Lake Ontario.[101]

Other *Campylobacter* Species

C. curvus, C. concisus, C. gracilis, C. rectus, C. showae, and *C. sputorum* generally are associated with the periodontal cavities of humans and animals and have no definitive association with human gastroenteritis. However, *C. curvus* has been isolated from patients with bloody and chronic diarrhea, and *C. curvus* and *C. rectus* have been reported as the cause of extraoral abscesses in humans.[102–104] Reports of the isolation of *C. concisus* from nonoral human clinical specimens (from blood and stool of patients with diarrhea, and from the foot of a diabetic patient with osteomyelitis) suggest that this organism can be a human pathogen.[105] *C. concisus* has been identified in 0.7% to 9% of stool samples from individuals with diarrhea.[106] However, whether *C. concisus* is a cause of diarrhea remains uncertain because it has been found in stools from healthy controls (children and adults) as often as in those with diarrhea.[6,106] It may be an opportunistic pathogen causing diarrhea in immunocompromised patients.[107] *C. concisus* has been identified in adults and children with Crohn disease and ulcerative colitis. It is unclear whether the organism plays a causative or opportunistic role in inflammatory bowel disease.[106,108–110]

C. hyointestinalis has been associated with human disease. In two studies, the rates of diarrhea due to *C. hyointestinalis* were 0.01% and 0.08% of all *Campylobacter*-associated episodes.[4,87] Other reports have described this organism as an uncommon cause of diarrhea or BSI.[111–114]

Capnocytophaga Species

Lorry G. Rubin

Capnocytophaga is a genus in the family Flavobacteriaceae encompassing a group of slow-growing, capnophilic (carbon dioxide–loving), facultative anaerobic, gram-negative fusiform bacilli. The 9 species are divided into two groups, with 7 in the "human" group (formerly classified as Centers for Disease Control and Prevention [CDC] biogroup dysgenic fermenter [DF]-1), which colonize the oral cavity of humans and 2 species in the zoonotic group (CDC biogroup DF-2), which are distinguishable from human *Capnocytophaga* because they are oxidase and catalase positive and colonize the oral cavity of dogs and cats.[1] Recovery in culture requires incubation in an environment with enhanced carbon dioxide concentration under aerobic or anaerobic conditions. Colonies are detectable after 2 to 4 days or longer incubation on several media, including blood agar; growth does not occur on MacConkey agar. Generally, species in this genus ferment carbohydrates, except mannitol and xylose.[1] Species can be distinguished by means of DNA hybridization, 16S rRNA analysis, or matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) spectrometry.[2–4] These two groups are considered separately because the patient population, epidemiology, and clinical features of infection are distinct.

Human *Capnocytophaga*

Microbiology and Epidemiology

The human *Capnocytophaga* spp.—*C. ochracea, C. gingivalis, C. sputigena, C. haemolytica, C. granulosa, C. leadbetteri,* and genospecies AHN8471—are normal flora of the gingival sulci of humans.[1,3,5] Identification by conventional tests frequently is not successful. 16S rRNA polymerase chain reaction (PCR)–restriction fragment length polymorphism or sequencing is used to identify species,[2] but MALDI-TOF may be useful for rapid identification.[3] Human *Capnocytophaga* spp., most commonly *C. ochracea*, cause invasive infection in the presence of neutropenia and oral mucosal ulceration, which often is cancer chemotherapy induced. This implicates the neutrophil specifically as important in host defense. Possible virulence factors include a serum-resistant phenotype, production of immunoglobulin A protease, and bacterial factors that interfere with host responses to infection, such as neutrophil migration.[6]

Clinical Manifestations and Treatment

The most significant infections are bloodstream infections (BSIs) (occasionally polymicrobial) in immunosuppressed children or adults, especially those with malignancies or recipients of stem cell transplantation.[6] These patients generally are neutropenic and have oral lesions such as mucositis or aphthous stomatitis.[7] Based on series of cases reported from France[7] and Spain,[8] the mortality rate associated with BSI is <2%. *Capnocytophaga* spp. have been recovered from other infected sites such as the lung, pleural space, eye, brain, wounds, heart, bone, and joints in immunocompetent patients, commonly in association with other bacteria.[9] *Capnocytophaga* spp. have been documented as a cause of chorioamnionitis[10] and early-onset sepsis in premature neonates[10–12] and are important pathogens in juvenile periodontitis.

Although many isolates are susceptible to penicillin, strains resistant to penicillin and cephalosporins due to production of β-lactamase are common. Some strains produce extended-spectrum β-lactamases that inactivate third-generation cephalosporins.[13] Resistance to multiple other antimicrobial agents has been reported.[7,10,14] Imipenem or a β-lactam–β-lactamase inhibitor combination is highly active against *Capnocytophaga;* either can be considered a drug of first choice until results of antibiotic susceptibility testing, including a test for β-lactamase production, is available.[15] Clindamycin, chloramphenicol, and tetracycline show good activity, and linezolid has been used successfully.[16,17] Ciprofloxacin and trimethoprim-sulfamethoxazole have variable activity and aminoglycosides, metronidazole, and vancomycin generally lack activity.

Zoonotic *Capnocytophaga*

Microbiology and Epidemiology

Both *C. canimorsus* (originally called CDC bigroup DF-2) and *C. cynodegmi* (CDC biogroup "DF-2 like")[18] are found commonly in the oral flora of dogs[19–21] and cats.[20,21] *C. canimorsus,* the predominant pathogen, resists phagocytic killing by human polymorphonuclear leukocytes[20,22] and causes invasive disease in asplenic hosts and patients with alcoholic cirrhosis, implicating the spleen as important for protection against invasive infection. Infections with *C. canimorsus* are zoonotic; infected patients report a dog bite or scratch or at least dog exposure (or much less commonly, cat exposure) before the onset of infection.[20,23,24] Most cases have occurred in adults, although infections have been reported in children, including neonates.

Clinical Manifestations and Treatment

Septicemia, in some cases with associated cellulitis, is the most common clinical infection due to *C. canimorsus,* occurring about 5 days (range, 1–8 days) after a dog (or rarely cat) bite or exposure to saliva.[20,23,24] Disseminated intravascular coagulopathy, purpura fulminans, and peripheral gangrene resulting in amputations can accompany sepsis. A mortality rate of 24% has been estimated.[20] Meningitis also occurs and has a lower case-fatality rate than septicemia.[20,25] Localized cellulitis without sepsis after a dog-bite wound occasionally occurs, and endocarditis, pneumonia, vertebral osteomyelitis, and brain abscess are reported. *C. cynodegmi* causes localized wound infection but rarely causes BSI. Although septicemia due to *C. canimorsus* can occur in immunologically normal hosts, many patients have an underlying condition, specifically asplenia or alcohol abuse or have received corticosteroid therapy.[20,24] Infection is fulminant in more than one half of asplenic patients.[18] Thrombotic thrombocytopenic purpura and hemolytic uremic syndrome have been reported in adults with *C. canimorsus* septicemia.[26]

Diagnosis is confirmed by culture of blood or cerebrospinal fluid. High-grade bacteremia can occur in asplenic patients particularly, and Gram stain of a buffy coat smear of blood may reveal organisms. In blood cultures, growth may be detected first in the anaerobic bottle, and blind subculture on enriched media may be needed because of inhibition of growth in the presence of sodium polyanethol sulfonate.[1] Isolates can be identified rapidly using MALDI-TOF.[4] Strains are susceptible to penicillin, except for 2 reports of resistance,[20] as well as to some cephalosporins, chloramphenicol, clindamycin, erythromycin, and tetracycline.[15] Susceptibility to aminoglycosides and trimethoprim-sulfamethoxazole is variable, and strains are resistant to aztreonam. Asplenic patients should be given penicillin prophylactically after a dog bite in an attempt to prevent this life-threatening infection (see Chapter 88).

Chlamydophila (Chlamydia) pneumoniae

Samir S. Shah

The Pathogen

Chlamydiae are obligate intracellular pathogens, which former genus *Chlamydia pneumoniae* has been reclassified (somewhat controversially[1]) through genome sequencing and comparative analysis of the ribosomal operon to *Chlamydophila pneumoniae,* with three biovars—human (TWAR), koala, and equine.[2] In this chapter, the term *C. pneumoniae* will refer to *Chlamydophila pneumoniae,* biovar TWAR, the agent causing infection in humans.

C. pneumoniae was first described as a human respiratory tract pathogen in the mid-1980s.[3,4] This obligate intracellular pathogen causes atypical pneumonia and upper respiratory tract disease and has been associated with a number of nonrespiratory conditions. *Chlamydia* spp. are classified as bacteria because of the ability to reproduce by binary division. Like *Chlamydia trachomatis* and *Chlamydophila psittaci, C. pneumoniae* has a biphasic developmental cycle of replication. The infectious bacterial form, known as the elementary body, enters the eukaryotic cell by endocytosis, resides within a cytoplasmic inclusion, and then transforms into a vegetative form (the reticulate body) to replicate by binary fission.

As the inclusion fills with progeny, chlamydiae transform back into the metabolically inactive but infectious elementary body and are released through host cell rupture or fusion of the inclusion with the host cell plasma membrane.

Epidemiology

C. pneumoniae is a common infection worldwide.[5–10] Variable quality of diagnostic assays and lack of standardization remain important challenges to a precise description of the epidemiology, but many retrospective serologic studies, as well as prospective studies using culture and polymerase chain reaction (PCR) testing, have identified the mode of transmission, incidence of disease, and clinical characteristics of infection.[3,5,11–15]

Infection occurs most commonly in late winter or early spring.[16] The age at which primary infection apparently occurs differs according to the testing tools used. Population-based serologic studies indicate that acquisition of specific antibody occurs most often in children between 5 and 15 years of age[17]; the seroprevalence in this age group is approximately 30%.[18] New or repeat infections continue through adolescence and adulthood, culminating in 70% to 80% seropositivity in elderly patients.[19] Acute infections (either primary infection or reinfection) are most common in school-aged children. In a prospective population-based study in Seattle, the incidence of acute infection by age groups per 100 person-years was as follows: 0 to 4 years (no cases); 5 to 9 (9.2); 10 to 14 years (6.2); 15 to 19 years (2.2); and ≥20 years (1.5).[17] In contrast, a population-based study in Thailand identified rates of *C. pneumoniae* pneumonia of 2–20 per 100,000 population, with the highest rates occurring in those younger than 1 year and older than 65 years.[20] If culture or PCR testing is used for such studies, colonization (or possibly infection) in younger children is identified commonly in the absence of a detectable antibody response.[12,15,21,22] Whether the absence of a serologic response in young children results from an insensitive test or from the absence of tissue invasion remains unresolved. *C. pneumoniae* was isolated from the nasopharynx or throat of 1% to 10% of healthy children and can be identified by PCR testing in 5% to 25% of children who attend childcare centers; those with respiratory tract symptoms and those from large families had the highest rates of identification of *C. pneumoniae*.[11,12,14,23–26]

C. pneumoniae is shed from the respiratory tract during the acute clinical illness and for up to 1 year later.[24] Subclinical infection with antibody response also is common.[17,23,24,27–29] It is not known whether the presence of symptoms increases the likelihood of transmission. Animal experiments suggest that aerosolized particles are an inefficient means of spreading *C. pneumoniae.* Although the organism remains viable only briefly on skin, it survives for 20 to 30 hours on environmental surfaces, suggesting that direct inoculation may be the predominant mode of transmission in clinical settings.[13]

Among military trainees in Finland, attack rates during a *C. pneumoniae* epidemic ranged from 60 to 84 per 1000 exposed men.[29] Attack rates during an outbreak of *C. pneumoniae* respiratory infections among Air Force cadets ranged from 1.5%–3.4%, and rates were highest among freshman military recruits, who tend to spend more time in close proximity to one another.[30] The outbreak ended after 8 months, possibly related to the movement of cadets off base after senior graduation. Attack rates were higher during institutional outbreaks, ranging from 44%–68% among nursing home residents and 22%–34% among nursing home staff.[31,32] The incubation period is 2–4 weeks as determined by the temporal clustering of cases during institutional[32] and military[29] outbreaks. Protracted epidemics of *C. pneumoniae* infection can occur in some settings. Epidemics among military trainees in Finland lasted approximately 6 months.[29] Some evidence points to epidemic periods occurring every 6 months to 3 years, superimposed on low levels of endemic *C. pneumoniae* infection.[4,27,29]

Clinical Manifestations

C. pneumoniae infects the upper respiratory tract epithelium of young children, where it occasionally causes or contributes to acute otitis media and sinusitis, as well as prolonged cough illness and community-acquired pneumonia. *C. pneumoniae* has been identified by culture and PCR testing in middle-ear fluid specimens from approximately 5% of children with acute otitis media.[11,12,33] Most often, another bacterial pathogen is found concurrently, and infection resolves in the absence of therapy directed at *C.*

pneumoniae. The organism has not been detected in individuals with chronic middle-ear effusions.[34] *C. pneumoniae* can be a cause of prolonged cough illness. The organism has been detected in 5% to 17% of individuals with prolonged cough; the clinical features resemble pertussis.[14,35,36] In patients with prolonged cough during outbreaks of pertussis-like illness, the mean duration of cough associated with *C. pneumoniae* infection has been 25 to 30 days, compared with 50 days for cough associated with *Bordetella pertussis*.[14,37,38] *C. pneumoniae*–associated fever and upper respiratory tract symptoms, including sore throat and hoarseness, can be self-limited or can progress to coughing and lower respiratory tract involvement.[15,21,39]

C. pneumoniae is a relatively uncommon cause of severe pneumonia in children. Earlier studies implicated *C. pneumoniae* in 5% to 14% of cases of pediatric community-acquired pneumonia.[5,10,15,25,40–47] However, *C. pneumoniae* was identified using a nasophyarngeal swab PCR test in only 0.5% of 2222 children hospitalized with radiographically confirmed community-acquired pneumonia at 3 US hospitals in 2011–2012.[48] In India, *C. pneumoniae* infection was identified by serologic testing in 1.1% of 2345 children younger than 12 years who met the World Health Organization definition of pneumonia in 2011–2013.[49] The illness tends to have a subacute onset, indistinguishable from that due to *Mycoplasma pneumoniae* or influenza. More than one half of infected patients have fever, cough, shortness of breath, chills, nausea, headache, and myalgia.[39,50] Crackles, wheezing, and rhonchi often are detected on physical examination. Chest auscultation and radiograph can indicate pneumonia even when respiratory tract symptoms are mild. Because of the prolonged and relatively mild nature of initial symptoms, the patient may seek medical attention >1 week after onset of illness, at which time fever and symptoms of systemic illness may have resolved.[39] *C. pneumoniae* infections cannot be differentiated reliably from other causes of pneumonia in children. Among adults requiring hospitalization for community-acquired pneumonia, patients with *C. pneumoniae* etiology were more likely than those with bacterial etiology to have a duration of illness >7 days (odds ratio, 3.5; 95% confidence interval, 1.3–9.4) and less likely to have a productive cough (odds ratio, 0.3; 95% confidence interval, 0.1–0.7).

C. pneumoniae has been associated with severe illness in sporadic case reports. *C. pneumoniae* was isolated from culture of the respiratory tract and pleural fluid of a previously healthy adolescent boy with severe pneumonia complicated by respiratory failure and parapneumonic effusions.[51] A 13-year-old girl developed pneumonia and hemorrhagic pericarditis; *C. pneumoniae* was detected in the pericardial fluid by PCR.[52] Encephalitis has been associated with *C. pneumoniae* in pediatric reports.[53–55] A 12-year-old girl developed concomitant lower respiratory tract infection and encephalitis; *C. pneumoniae* DNA was detected by multiplex PCR in endotracheal secretions, and immunoglobulin M (IgM) and IgG antibodies were detected in serum, but not cerebrospinal fluid specimens.[53]

Most studies that include appropriate control groups fail to demonstrate an association between asthma and acute or chronic *C. pneumoniae* infection.[56–60] For example, *C. pneumoniae* was identified in 3.4% of children during an asthma exacerbation, in 6% of children during an initial episode of wheezing, and in 2.5% of patients with stable asthma or allergic rhinitis.[56] However, Teig and colleagues detected *C. pneumoniae* by PCR from 24% of children with stable asthma but from 0% of healthy nonasthmatic children[61]; it is unclear why *C. pneumoniae* was detected less frequently in the control population in this study compared with previous studies.

Nonstandardized laboratory testing has resulted in widely varying and often unconfirmed reports of new clinical associations of *C. pneumoniae,* including Alzheimer disease, atherosclerotic cardiovascular disease, multiple sclerosis, meningoencephalitis,[62–64] pyoderma gangrenosum,[65] and a variety of other diseases in children and adults (Table 166.1). *C. pneumoniae* was identified by immunohistochemistry in cardiovascular tissue of sporadic cases of Kawasaki disease.[66] This association was not confirmed in a case-control study.[67]

TABLE 166.1

Diseases Associated With *Chlamydia pneumoniae* Infection

Pathologic Role Established	Association Supported by Several Lines of Evidence
Pneumonia	Otitis media
Prolonged cough illness	Cardiovascular disease
Acute bronchitis	Asthma

SPECULATIVE ASSOCIATIONS	
Meningoencephalitis	Multiple sclerosis
Alzheimer disease	Myalgia
Kawasaki disease	Conjunctivitis
Lung cancer	Arthritis
Hypertension	Adult respiratory distress syndrome
Erythema nodosum	Chronic fatigue syndrome
Chronic bronchitis	Ischemic stroke

Modified from Sanchez F, Dowell S. *Chlamydia pneumoniae* infection in children: a pediatric infection with possible consequences in adults? Pediatr Infect Dis J 1999;19:367–373.

Laboratory Diagnosis

Recommendations for standardized approaches to culture, PCR testing, serology, and immunohistochemistry were published by the US Centers for Disease Control and Prevention (CDC) and the Canadian Laboratory Centres for Disease Control (LCDC).[68] However, only one of the many diagnostic assays used worldwide to identify *C. pneumoniae* has been approved by the US Food and Drug Administration (FDA) for clinical use.[69] This lack of standardization has resulted in substantial variation in interlaboratory test performance, even when using the same test and diagnostic criteria.[70]

Serologic testing has been the primary means of clinical diagnosis because of its widespread availability and relative simplicity. However, many of the available assays, including complement fixation, whole-inclusion fluorescence, and various enzyme immunoassays, perform poorly or have not been adequately validated; microimmunofluorescence testing remains the only endorsed serologic approach, despite limitations.[68] During primary infection, IgM antibody appears 2 to 3 weeks after illness onset. IgG antibody may not reach high titer until 6 to 8 weeks after illness onset. Confirmation of primary acute infection requires an IgM titer of 1 : 16 or higher, or a fourfold rise in IgG titer between acute and convalescent serum specimens. During reinfection IgM antibody may not appear, and IgG antibody titer can rise within 1 to 2 weeks of infection.[68] Criteria proposed in the past, including a single IgG titer >1 : 512 or elevated IgA antibody, are no longer endorsed because of low specificity. IgG titers ≥1 : 16 are consistent with previous exposure and are found in approximately one-half of adults. A single elevated IgG titer does not confirm the diagnosis *C. pneumoniae* infection.

The organism or its DNA can be identified by culture or PCR testing from specimens from nasopharyngeal or throat swabs, sputum, blood, or tissue. Culture has been considered the reference-standard diagnostic method. A specimen for culture can be collected on a Dacron-tipped, wire-shafted, or plastic-shafted swab. The specimen, transported in appropriate media at 4°C, is then centrifuged onto HEp-2 (human epithelial cell line type 2) or HL (heteroploid line with a slow life cycle) cell lines, passaged twice, and examined at 3 to 7 days after staining with monoclonal antibodies to identify the *C. pneumoniae* inclusions. Observation of inclusions constitutes a presumptive positive result; confirmation requires either successful passage of the isolate or confirmation with PCR. Swabs with calcium alginate or cotton tips and wooden shafts can inhibit the growth of the organisms, depending on the adhesive used. Specimens that cannot be processed within 24 hours should be frozen and held at −70°C.

Only 4 of >30 published PCR assays met validation criteria proposed by the CDC and LCDC.[68,70] Validation in these 4 studies was primarily analytical; extensive validation on clinical specimens has not yet been performed. Only the FilmArray Respiratory Panel, a multiplex PCR panel that also detects multiple viruses, has received approval by the FDA for detection of *C. pneumoniae* in respiratory or other specimens.[69,71] Reports of PCR detection in clinical specimens, as well as in research studies on atherosclerotic plaques, peripheral blood mononuclear cells, brain, lung, and other tissues, should be interpreted in the context of other confirmatory information. Identification of *C. pneumoniae* in the respiratory tract by culture or PCR testing does not establish causation of disease because of prolonged shedding.[24,28,72] Despite CDC recommendations, there remains a high degree of heterogeneity in serologic methods and diagnostic criteria used in studies purporting *C. pneumoniae* respiratory tract infections.[70]

C. pneumoniae can be detected in tissue by PCR testing or in situ hybridization, but immunohistochemical techniques have been used most commonly. The prevalence of the organism in arterial plaques has varied by report from 0% to >50%, highlighting the importance of appropriate selection of the monoclonal antibody, use of appropriate controls in the staining procedures, and careful interpretation to exclude false-positive staining results.[68,73]

Routine laboratory studies do not distinguish *C. pneumoniae* from other causes of acute respiratory tract infection.[15,21,39] The erythrocyte sedimentation rate typically is elevated (range, 21–75 mm/hr). Peripheral white blood cell count can be elevated or normal, usually with neutrophil predominance.[50] Radiographic appearance of pneumonia usually is bilateral ground-glass or nodular infiltrates, although unilateral alveolar infiltrate and pleural effusion have been reported in more than one fourth of cases.[50,51,72,74]

Treatment

Standards for in vitro susceptibility testing have not been established, but *C. pneumoniae* appears to be susceptible to most antibiotics that inhibit protein or DNA synthesis, including tetracyclines, macrolides, ketolides, and most fluoroquinolones (e.g., levofloxacin and moxifloxacin, but not ciprofloxacin); *C. pneumoniae* is resistant to sulfa drugs.[72,75–78] Microbiologic eradication of the organism from the nasopharynx occurs in 70% to 90% of children with *C. pneumoniae* pneumonia after a 10-day course of erythromycin or clarithromycin, or a 5-day course of azithromycin.[21,79,80] Clinical resolution occurs in a high percentage of children who are not treated[81] or who are given a β-lactam agent predicted to be ineffective.[11,79] Typical treatment regimens, when prescribed, are 14–21 days for tetracycline or doxycycline, 14 days for erythromycin, 7–14 days for fluoroquinolones or clarithromycin, and 5 days for azithromycin. In some patients, clinical symptoms and persistent isolation of the organism occur despite 10- to 30-day courses of appropriate therapy.[28,82] The role of prolonged therapy in patients with persistent or relapsing symptoms is not clear.

Complications

Complications of acute *C. pneumoniae* infection are rare. The possibility that *C. pneumoniae* can establish a state of persistent infection has lent plausibility to a number of associations with chronic diseases. The association between *C. pneumoniae* and atherosclerotic cardiovascular disease is based on higher prevalence of serum antibodies in patients with coronary heart disease than in controls,[73] detection and culture of the organism in atheromatous plaques,[73,83,84] and animal studies and small human trials suggesting a benefit of treatment with macrolides.[85–87] A meta-analysis has failed to support a significant serologic association,[88] and large, prospective, randomized trials have thus far not found evidence of treatment benefit of the magnitude suggested by the earlier studies.[89] A longitudinal study of children found no association between repeated anti-*Chlamydophila* treatments in childhood and early vascular changes, suggesting that antimicrobial therapy does not prevent atherogenicity potentially associated with repeated infectious insults.[90] Although studied less extensively, evidence is conflicting for *C. pneumoniae* as a causative agent in Alzheimer disease,[91–93] ischemic stroke,[94,95] asthma,[58,59,96,97] multiple sclerosis,[98–101] Kawasaki disease,[66,67] and other conditions (see Table 166.1).[62,65,102]

Chlamydia trachomatis

Toni Darville, G. Ingrid J.G. Rours

The Pathogen

Chlamydiae are obligate, intracellular, nonmotile, gram-negative bacteria with a unique biphasic developmental cycle consisting of extra- and intracellular forms. Chlamydiae have an outer membrane that contains lipopolysaccharide (LPS) and membrane proteins. Peptidoglycan is present in the septum of dividing bacteria.[1] Although chlamydiae contain DNA, RNA, and ribosomes, they obtain high-energy phosphate compounds from the host cell. *Chlamydia trachomatis* encodes an abundant protein called the major outer membrane protein (MOMP or OmpA) that is surface exposed and is the major determinant of serologic classification.

Life Cycle

The biphasic developmental cycle of chlamydiae is unique among microorganisms and involves two highly specialized characteristic morphologic forms, as shown in Fig. 167.1. The extracellular form or *elementary body* (EB) has a rigid, thick outer membrane that contains extensive disulfide cross-links both within and between outer membrane proteins and is stable outside of the cell. The small (350 nm in diameter) EB is infectious but inactive metabolically.

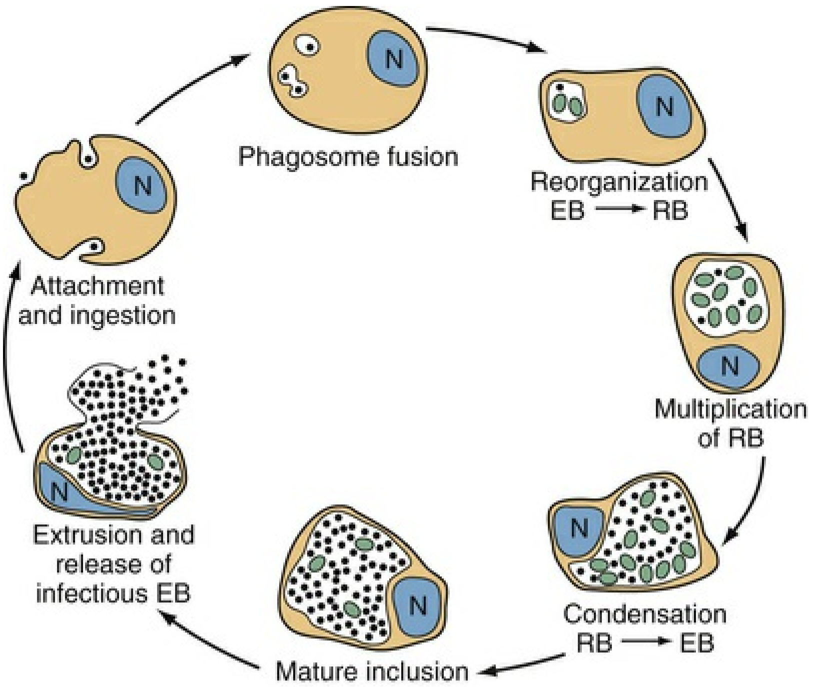

FIGURE 167.1 Life cycle of *C. trachomatis* in tissue culture. *EB,* elementary bodies; *N,* nucleus; *RB,* reticulate bodies. (Redrawn from Jones RB. *Chlamydia trachomatis* (trachoma, perinatal infections, lymphogranuloma venereum, and other genital infections). In: Mandell GL, Bennett JE, Dolin R [eds]. Principles and Practice of Infectious Diseases, 5th ed. New York, Churchill Livingstone, 2000, p. 1990.)

The developmental cycle is initiated when an EB attaches to a mucosal epithelial cell. A number of candidate adhesins have been proposed, but their identity and that of associated epithelial cell receptors remain uncertain. When inside the cell, the EB resides within a membrane-limited endosome and prevents fusion of the endosome with lysosomes, protecting itself from enzymatic destruction. Escaping from host attack by antibody or cell-mediated defenses, the EB enlarges and reorganizes into the replicative and metabolically active form, the *reticulate body* (RB). Chlamydiae hijack certain host cell signaling pathways to protect the cell from recognition and attack while preventing apoptosis and maintaining integrity of their host cells.[2]

RBs remain strictly intracellular, successfully parasitizing the host cell, synthesizing messenger RNA, dividing, and multiplying. As the RB divides by binary fission, it fills the endosome, now a cytoplasmic *inclusion,* with its progeny. After 48 to 72 hours, multiplication ceases and nucleoid condensation occurs as the RBs reorganize and transform again to new infectious EBs. Eventually, the host cell's nutrients are expended, and EBs are released from the cell by cytolysis,[3] exocytosis, or extrusion of the whole inclusion,[4] leaving the host cell intact. The last fact may explain the frequency of asymptomatic or subclinical chlamydial infections. The release of the infectious EBs allows infection of new host cells to occur.

Classification

The family Chlamydiaceae contains a single genus, *Chlamydia,* and 11 pathogenic species, which infect humans and a wide variety of animals; for example, *C. pneumoniae* infects humans, horses, koala, amphibians, and reptiles; *C. psittaci* 6BC infects birds and mammals; and *C. abortus* infects sheep, goats, cattle, and swine.[5] Humans are the natural host for the more than 18 serovars of *C. trachomatis*, divided into subgroups based on antigenic variation in the major outer membrane proteins (serovars) and clinical patterns of disease.[6,7] Trachoma is caused by serovars A, B, Ba, and C; oculogenital and neonatal disease by serovars B, Da, Ga, Ia, and D-K; and lymphogranuloma venereum (LGV) by serovars L1, L2, L2a, and L3.

Pathogenesis

LGV serovars can replicate in lymph nodes and macrophages, whereas replication of the other serovars of *C. trachomatis* is confined to mucosal epithelial cells. After an incubation period of 10 days (between 7 and 21 days) a variety of clinical manifestations can result from the host inflammatory response and tissue destruction. Primary infection is characterized by marked influx of neutrophils, especially early in infection.[8–11] Lymphocytes and plasma cells also participate in the primary response, but they appear later, concurrently with resolution of infection. In adult ocular and genital infections, plasma cells can be present in large numbers,[12–14] whereas in neonates and infants with ocular or respiratory tract infection, eosinophils and neutrophils predominate.[15]

The host is assumed to develop a protective immune response since chlamydial infections can be self-limited.[16,17] However, asymptomatic infection can be chronic, lasting for months or even years.[18,19] Although repeated infections are common, especially among high-risk adolescent women,[20] resistance to reinfection can develop. A recent study revealed that rates of reinfection over a 1-year follow-up period were lower (4.5%) in women who spontaneously cleared their infection compared with women who had persisting infection (16.5%).[17] Early detection and treatment may attenuate protective immunity in some patients.[21]

Epidemiology

C. trachomatis strains exhibit tissue tropism, with different strains infecting either the mucosa of the genital tract or the eye. *C. trachomatis* is the leading cause of bacterial sexually transmitted infection (STI) in the world. However, in endemic areas, mostly in Africa and the Middle East, *C. trachomatis* causes trachoma, the leading cause of preventable blindness worldwide.

The World Health Organization estimated that 92 million new cases of *C. trachomatis* infection occur annually worldwide.[22] It is estimated that >3 million chlamydial infections occur annually in sexually active adolescents and adults in the United States. Most infected men and women are either asymptomatic or minimally symptomatic, and diagnosis is a result of screening or because a contact is symptomatic. The rate of chlamydial infection reported to the Centers for Disease Control and Prevention (CDC) from 1993 through 2011 increased from 178 to 453.4 cases per 100,000 population.[23] Possible reasons for the increase are increased awareness and screening, increased use of nucleic acid amplification tests (NAATs), and improved reporting, as well as continuing high burden of disease. In 2013, 1,401,906 chlamydial infections were reported to the CDC. This is the first time since national reporting began that the rate of reported cases decreased. The reported number of cases of chlamydial infection was >4 times that of reported cases of gonorrhea. Table 167.1 outlines prevalence estimates reported for selected conditions and patient groups.[24–30]

TABLE 167.1

Prevalence of Chlamydial Genital Infection in Selected Patient Groups and Conditions

Subject Group or Condition	Females (%)	Males (%)
Adolescents	8–37	13–15
Adults (asymptomatic)	4–8	3–5
Adults (STD clinic)	>20	15–20
Gonorrhea	25–50	5–30
Mucopurulent cervicitis or nongonococcal urethritis	9–15	30–40
Pelvic inflammatory disease or epididymitis	8–54	50

STD, sexually transmitted disease.

Data collated from Centers for Disease Control and Prevention. Prevalence of *Chlamydia trachomatis* genital infection among persons aged 14−39 years—United States, 2007−2012. MMWR Morb Mortal Wkly Rep 2014;63:834−838.

Young age (<20 years) is the sociodemographic factor most strongly associated with chlamydial infection. A study in Louisiana public high schools revealed an overall prevalence of *C. trachomatis* of 6.5%, with rates among girls more than twice that of boys (9.7% vs. 4%).[31] In a study of more than 3000 sexually active adolescent girls attending middle school health centers in Baltimore, chlamydial infection was found in ~24% at the first visit and 14% at repeat visits; 14-year-old girls had the highest age-specific prevalence rate (28%).[26] Independent predictors of chlamydial infection failed to identify a subset of adolescent females with most infections.

Substantial racial and ethnic differences exist in the prevalence of chlamydial infections. In the United States a cross-sectional analysis in a prospective cohort study of a nationally representative sample of 14,322 young adults aged 18 to 26 years revealed the overall prevalence of chlamydial infection to be 4.2%.[32] Women (4.7%) were more likely to be infected than men (3.7%). Prevalence was highest among black women (14%) and black men (11%) and lowest among white women (2.5%), white men (1.4%), and Asian men (1.1%). Prevalence was highest in the South (5.4%) and lowest in the Northeast US. (2.4%). Significant geographic variation in prevalence rates occur in other countries as well; for example, in the Netherlands, rates as high as 16.2% occur among Antillean women compared with 1.8% among Dutch women.[33] Other predictors of incident chlamydial infection in young women include single marital status, having a new sex partner, smoking, having gonorrhea or bacterial vaginosis, and presence of high-risk carcinogenic human papillomavirus.[20,29,30] Use of progestin-only or combined estrogen and progestin contraceptives did not alter risk for incident infection in a study of young women at low to moderate risk (4% baseline infection rate).[29] Oral contraceptives had no effect on risk for chlamydial infection in a study of adolescents, but use of depot medroxyprogesterone acetate injections increased the risk for infection fivefold compared with nonhormone users.[34] In a prospective study in 948 Kenyan sex industry workers, users of oral contraceptives had increased risk for acquisition of *Chlamydia* (hazard ratio, 1.8; 95% confidence interval [CI], 1.1–2.9). Those using depot medroxyprogesterone acetate had significantly increased risk for *Chlamydia* infection (hazard ratio, 1.6; 95% CI, 1.1–2.4) but significantly decreased risk for pelvic inflammatory disease (PID) (hazard ratio, 0.4; 95% CI, 0.2–0.7).[35]

Partner transmission rates are approximately 65% and appear to be similar for female-to-male and male-to-female transmission.[36,37] The number of exposures or coinfection with *Neisseria gonorrhoeae* did not affect the transmission rate.

Clinical Manifestations

C. trachomatis infects susceptible squamocolumnar or transitional epithelial cells (e.g., mucous membranes of the conjunctivae, posterior nasopharynx, urethra, endocervix, and rectum).

Perinatal Infection

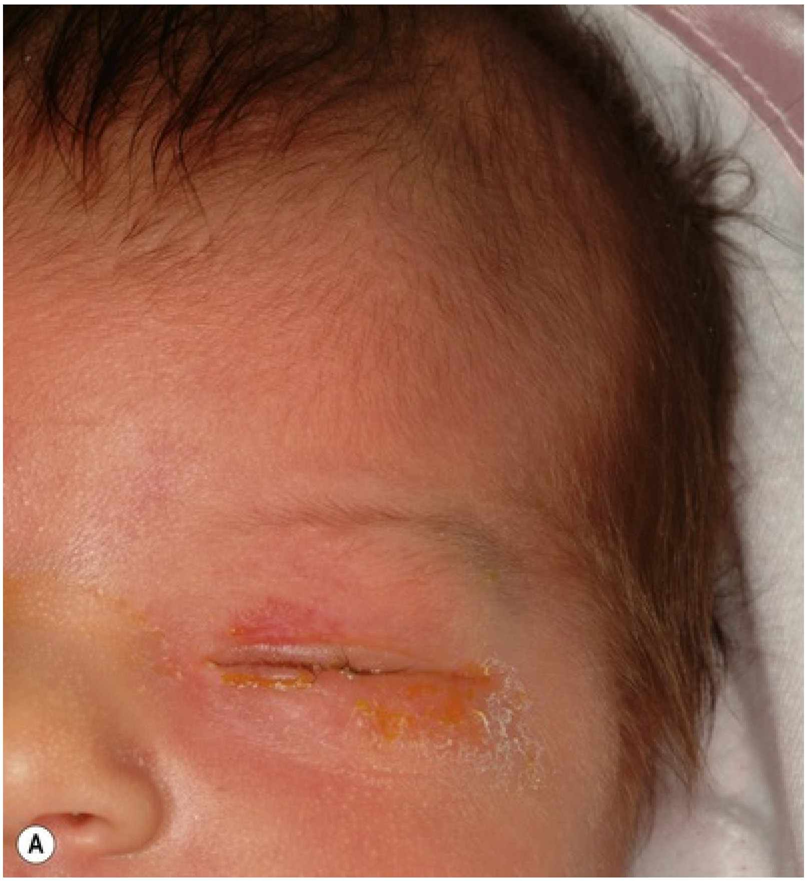
Neonatal infection generally is acquired during passage through an infected birth canal. In a recent Chinese study, the vertical transmission rate was 67% after vaginal delivery and 8% after cesarean delivery.[38] Prospective studies of infants born to women with chlamydial infection of the cervix show 50% to 75% risk that the infant will acquire *C. trachomatis* at one or more anatomic sites.[39–43] In infants exposed to *C. trachomatis,* risk for conjunctivitis is 20% to 50%, and risk for pneumonia is 5% to 20%.

In ~14% of infants born to women with chlamydial infection, asymptomatic rectal or vaginal *C. trachomatis* can be detected, which can persist for ≥18 months.[44] Persistence of *C. trachomatis* in the genital tract can confound evaluation for possible sexual abuse and requires thorough and appropriate investigation.[45]

Inclusion Conjunctivitis

C. trachomatis is the most common cause of ophthalmia neonatorum, the major clinical manifestation of neonatal chlamydial infection.[46] The usual incubation period is 5 to 14 days after birth, but symptoms can occur earlier after premature rupture of membranes or as late as 6 weeks after birth.[39] At least 50% of infants with chlamydial conjunctivitis have concurrent infection in the nasopharynx.

The most common symptom is watery ocular discharge that progressively becomes more purulent (95%), followed by swelling of the eyelids (73%) and conjunctival erythema (65%)[46] (Fig. 167.2). Most cases resolve spontaneously during the first few months of life. However, if the condition is untreated, chronic conjunctivitis can develop. Although conjunctivitis can be quite severe, corneal ulceration, scars, and pannus formation are rare, and recovery is expected without visual impairment.[47]



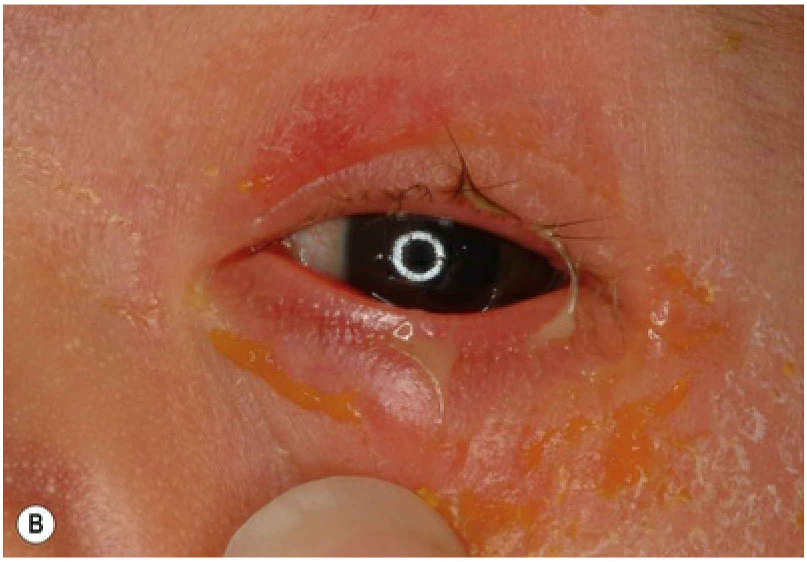


FIGURE 167.2 (A and B) A neonate with chlamydial conjunctivitis. (Courtesy of J. H. Brien ©.)

Chlamydial conjunctivitis must be distinguished from that produced by pyogenic bacteria, particularly *N. gonorrhoeae.* Gonococcal ophthalmia usually occurs earlier (around 2–5 days after birth) and usually progresses more rapidly. Clinical findings of neonatal conjunctivitis caused by *C. trachomatis, N. gonorrhoeae,* or other pathogens can be indistinguishable.

Pneumonia in Infancy

Pneumonia caused by *C. trachomatis* in infancy occurs characteristically between 3 and 12 weeks of age but sometimes can manifest later.[48–52] Characteristically, the infant has been symptomatic for 3 or more weeks before coming to medical attention. Most infants are only modestly ill and are afebrile. Symptoms of nasal obstruction and a pertussis-like (but nonproductive, staccato) cough gradually worsen over ≥1 week. Physical findings include tachypnea and rales but not wheezing. About 50% of the affected infants have a history or evidence of conjunctivitis. Laboratory findings include hyperinflation with symmetric interstitial infiltrates on chest radiography, peripheral eosinophilia (>400 cells/mm^3), and increased levels of serum immunoglobulins. *C. trachomatis* pneumonia in preterm neonates has been reported to manifest as early as 48 hours after birth, with idiopathic respiratory distress that improved initially but was complicated by apneic spells and feeding problems.[53–56]

Genital and Ocular Infections

C. trachomatis causes a variety of oculogenital infections in sexually active adolescents and adults, as well as in children who have been sexually abused (see Table 167.1).[57] Most infected persons are asymptomatic. In the National Longitudinal Study of Adolescent Health, 95% of *C. trachomatis*–infected people did not report symptoms in the 24 hours preceding specimen collection.[32] Among infected men, urethral discharge and dysuria were present only in 3% and 2%, respectively. Among infected women, vaginal discharge and dysuria were present only in 0.3% and 4%, respectively. Among patients reporting urethral discharge, the prevalence of chlamydial infection was high (38%) in men, but low (1%) in women. Of note, 6% of women reporting dysuria had chlamydial infection.

The incubation period for symptomatic males is 7 to 14 days. They may complain of dysuria, a slight, clear or mucopurulent urethral discharge, or stained underwear in the morning; or discharge may be detected only after penile stripping during genital examination by a healthcare provider.[58] The primary complications of chlamydial urethritis in men are epididymitis, reactive arthritis (including Reiter syndrome), and transmission to women. *C. trachomatis* and *N. gonorrhoeae* are the most frequent causes of epididymitis in men <35 years of age; urethritis also usually is present.

Although asymptomatic rectal carriage of *C. trachomatis* occurs in both infants[59] and adults,[60] *C. trachomatis* is a frequent cause of proctitis and proctocolitis in men who have sex with men.[61] Approximately 1% of men with nongonococcal urethritis develop acute aseptic arthritis of presumed immune-mediated etiology. One third of patients have the full complex of Reiter syndrome (arthritis, nonbacterial urethritis, and conjunctivitis); most such patients carry the histocompatibility antigen HLA-B27.[62]

The natural course of *C. trachomatis* infection in women was described in a study of Colombian women followed for a 5-year period using serotyping and polymerase chain reaction (PCR) on cervical-scrape samples.[18] Approximately 46% of infections, if not treated, were persistent at 1 year, 18% at 2 years, and 6% at 4 years of follow-up. Symptoms of *C. trachomatis* infection in women include a dysuria-pyuria syndrome, vaginal discharge, intermittent bleeding, and mild abdominal pain. The cervix can appear normal or can exhibit edema, erythema, friability, or mucopurulent discharge. In prepubertal girls, vaginitis can occur secondary to *C. trachomatis* infection of transitional cell epithelium. In contrast, the squamous epithelium of the adult vagina is not susceptible, and vaginal discharge generally reflects endocervical infection.

In some women, ascending infection of the genital tract develops, resulting in endometritis and salpingitis (Fig. 167.3). Eighteen (16%) of the infected asymptomatic adolescent women in one study who were monitored for ≥2 months became symptomatic, but <2% developed clinical PID.[63] A review of 24 studies examined PID diagnosis and sequelae after untreated chlamydial infection.[64] On average in high-risk settings, 2% to 5% of untreated females developed PID within the approximately 2-week period between testing positive for *C. trachomatis* and returning for treatment.[65,66] In several studies, repeated chlamydial infection was associated with PID and other reproductive sequelae, although it was difficult to determine whether there was stepwise increase with each recurrent episode.[65,67,68] No prospective study has directly assessed the risk for infertility after untreated *C. trachomatis* infection. However, according to the largest studies, after symptomatic PID of any cause has occurred, up to 18% of women can develop infertility.[69]

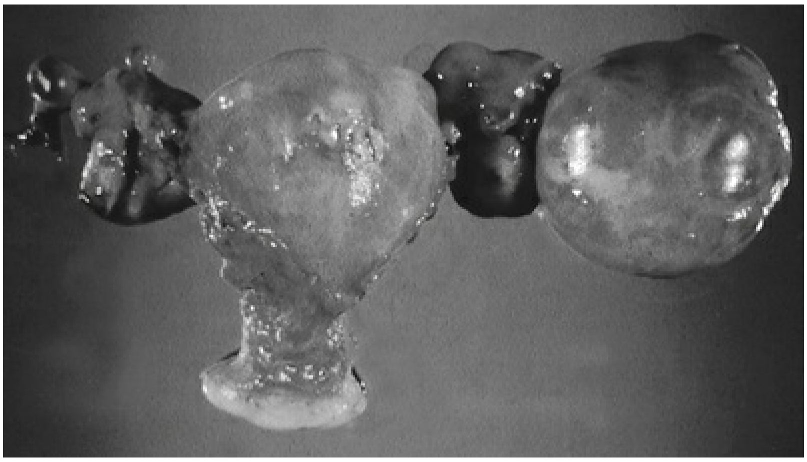

FIGURE 167.3 Pathologic specimen of uterus and salpinx from a patient with involuntary infertility and a history of repeated chlamydial infections.

C. trachomatis and *N. gonorrhoeae* are the most common causes of

PID, with more than one half of cases due to one or both organisms. The spectrum of PID associated with *C. trachomatis* infection ranges from asymptomatic to acute, severe disease with perihepatitis and ascites (Fitz-Hugh–Curtis syndrome). Compared with women who have gonococcal or nongonococcal-nonchlamydial salpingitis, women with chlamydial salpingitis are more likely to experience a chronic, subacute course with a longer duration of abdominal pain before they seek medical care.[70] Yet, they have as much or more tubal inflammation at laparoscopy.[71] Chronic infections, even if subclinical, can lead to infertility and ectopic pregnancy.

Adolescents and adults with genital tract disease presumably can autoinoculate their eyes, leading to inclusion conjunctivitis.[72,73] Additionally, infection can follow exposure to infected eye secretions without sexual contact or can occur in conjunction with unrecognized genital infection that has resolved. Acute follicular conjunctivitis is typical. Symptoms are those of a foreign body sensation in the eye. The infection usually resolves without complications but, if untreated, can persist for months and can result in scarring.

Infection and Pregnancy

C. trachomatis infection can negatively influence pregnancy.[74] Previous chlamydial infection has been associated with increased risk for ectopic pregnancy, as evidenced by serologic studies, isolation of *C. trachomatis* from fallopian tubes, and chlamydial DNA detection from cervical, endometrial, or salpingectomy tissues.[75,76] In addition, *C. trachomatis* infection has been associated with spontaneous abortion, stillbirth, and preterm delivery.[77–79] In a nationwide study in New South Wales of first-time mothers having singleton births, prior history of infection with chlamydia was associated with a 40% increased rate of stillbirth and a 17% increased risk for preterm birth.[77] Another study revealed a threefold increased risk for preterm delivery in women with cervical infection at 24 weeks of gestation.[79] Evidence that preterm delivery is associated with *C. trachomatis* infection has increased with the use of NAAT.[80] In a Dutch noninterventional prospective cohort study among pregnant women, chlamydial infection was associated with preterm delivery before 32 weeks (odds ratio [OR], 4.35; 95% CI, 1.3, 15.2) and 35 weeks (OR, 2.66; 95% CI, 1.1, 6.5) of gestation.[33] Infection of the placenta may lead to preterm delivery. Among 304 pregnant women with delivery before 32 weeks of gestation, *C. trachomatis* was detected in 25% of placentas. Histologic evidence of inflammation was present in 54% of placentas with *C. trachomatis* versus 36% without.[81] Chlamydial infection correlated with the progression and intensity ($P = 0.007$) of maternofetal placental inflammation.

Lymphogranuloma Venereum

LGV is an STI caused by the L1 to L3 serovars of *C. trachomatis.* The bubonic form is endemic in tropical and subtropical areas but is reported rarely in the US. Classically, LGV is a disease of the lymphatic tissue with acute and chronic manifestations.[82] The primary lesion is a small, inconspicuous, asymptomatic genital papule or ulcer that heals without a scar. Days to weeks later, unilateral acute lymphadenitis with bubo formation occurs at the site of lymphatic drainage of the primary lesion; acute hemorrhagic proctitis develops after a rectal lesion. Systemic symptoms can include fever, myalgia, or headache. About one third of inguinal buboes become fluctuant and rupture; the remainder involute slowly. Although most patients recover from LGV after this secondary stage, a small number develop a chronic inflammatory response with fibrosis (owing to the persistence of chlamydiae in anogenital tissues) that can result in chronic genital ulcers or fistulas, rectal strictures, or genital elephantiasis.

Rare in the Western world before 2003, outbreaks of LGV proctitis have been reported in the Netherlands,[83] Europe, North America, and Australia among men who have sex with men.[84] Most were HIV infected with high-risk sexual behavior and a high rate of concomitant STIs, including hepatitis C.[85]

Ocular Trachoma

Trachoma still is one of the world's leading causes of blindness; approximately 30% of the children in a holoendemic area are at risk for blindness due to severe trachoma.[86] Extensive studies in Taiwan revealed the importance of reinfection in the pathogenesis of trachoma.[87] Both pannus formation (the superficial vascularization that is pathognomonic of trachoma) and progressive disease with scarring are believed to be due to cycles of active infection and resolution repeated over many years.

In areas that are endemic for trachoma, infections occur early in life, and active disease persists for several years. Poor hygiene and presence of eye-seeking flies enhance transmission. Initially, chronic follicular conjunctivitis typical of inclusion conjunctivitis develops, followed by more intense inflammation of the conjunctivae and then scarring of the tarsal conjunctiva. After severe scarring of the inner surface of the lids, trichiasis (in-turning of the eyelashes) often develops, resulting in further corneal ulceration, scarring, opacification, and loss of vision. *C. trachomatis* can be isolated from conjunctival scrapings and nasopharyngeal cultures obtained from young children with active trachoma. The clinical spectrum of trachoma can vary from mild to severe; a simplified World Health Organization grading scheme can be used for standardized clinical assessment.[88,89] Young preschool children who have persistent or severe disease and chronically shed *C. trachomatis* act as an important reservoir of infection within a family unit.[90]

Laboratory Diagnosis

The diagnosis of trachoma in endemic areas can be based on clinical findings. Other chlamydial infections generally require laboratory confirmation to distinguish them from other conditions. A positive laboratory test for *C. trachomatis* can be used for patient education and to improve adherence to treatment regimens and increase the likelihood of referral of sexual partners. The development of tissue cell culture methods in the 1960s was a major advance, but they have been replaced by NAATs as methods of choice for diagnosis.

Definitive diagnosis of chlamydial infection, as would be required in a medicolegal setting (i.e., suspected sexual abuse or rape), requires isolation of *C. trachomatis* in cell culture or a positive NAAT confirmed by a second NAAT that targets a different gene sequence.[91]

Diagnostic Specimens

Many screening tests for *C. trachomatis* require appropriately handled samples containing columnar epithelium from mucosal sites rather than exudate.

The discomfort caused by obtaining a urethral swab in males has precluded its widespread use in asymptomatic men. A dipstick test for leukocyte esterase performed on the first portion of voided urine is a cost-effective and relatively sensitive screen (72%–95%) in asymptomatic young men.[92] Sediment from leukocyte esterase −positive urine then is used for a nonculture diagnostic test and, in members of low-risk populations, as a second confirmatory test. When feasible, urine NAAT provides a more sensitive and equally noninvasive method of detection.

Diagnostic Methods

Cell Culture.

Use of chlamydial transport media containing antibiotics maximizes recovery. Swabs used to obtain a specimen should have plastic or metal shaft and a tip made of cotton or Dacron because this causes less inhibition than nylon or alginate. Storage at 4°C or maintenance at –70°C is required if inoculation within 24 hours is not possible. Cycloheximide-treated McCoy or HeLa cell lines are used most frequently for isolation. Centrifugation techniques enhance absorption of chlamydiae to cells. Intracytoplasmic inclusions can be detected at 48 to 72 hours with species-specific immunofluorescent monoclonal antibodies or Giemsa or iodine staining.

Nonculture Tests.

NAATs have a higher sensitivity than all other tests, while retaining high specificity when cross-contamination is avoided.[93] NAATs have US Food and Drug Administration approval for testing cervical swabs from women, urethral swabs from men, and urine from men and women. NAATs detect *C. trachomatis* in urine or in self-administered vaginal swab specimens with sensitivity comparable with clinician-obtained urogenital swab specimens, which makes noninvasive testing possible.[94,95] Data suggest that NAATs are equivalent to or better than culture for the detection of

C. trachomatis in the conjunctiva and nasopharynx of infants[96] and are used currently in evaluation of newborns with conjunctivitis or pneumonia.

Direct fluorescent antibody (DFA) assays use fluorescein-conjugated monoclonal antibodies to stain chlamydial antigens in smears. DFA assays are cleared by the US Food and Drug Administration for use with pharyngeal specimens and potentially have high specificity if a *C. trachomatis*–specific stain is used. The tests also perform well on conjunctival specimens, with sensitivities >90% and specificities ≥95% compared with culture.[97,98] DFA assays that use antibodies specific for chlamydial MOMP are highly specific, but certain commercial kits using anti-LPS antibodies can lead to false-positive results.

Enzyme immunoassays detect chlamydial LPS but are less sensitive than culture and NAATs, and there is a potential for false-positive results caused by cross-reaction with LPS of other microorganisms, including other *Chlamydia* species.[99]

Serologic tests are of limited value in individual cases and are used primarily for population studies. However, serology can be used to detect *C. trachomatis* in women with tubal-factor infertility and in newborns. The detection of specific serum immunoglobulin M (IgM) or tear IgA antibodies in an individual is suggestive of current infection. In infants IgM levels often are elevated with neonatal pneumonia, but not with conjunctivitis.[100] Cytology is used mainly to diagnose conjunctivitis. Characteristic glycogen-containing intracytoplasmic inclusions can be identified in Giemsa-stained conjunctival scrapings from up to 90% of infants and 50% of adults who have inclusion conjunctivitis but from only 10% to 30% of patients who have active trachoma.[101] This method allows for visualization of *C. trachomatis* and other bacteria, such as gonococci, and of cytologic findings suggesting viral infection. Glycogen staining does not exclude other pathogens, is not helpful in patients with mild disease, and is not recommended for evaluation of endocervical specimens.

Treatment

Antibiotics against *C. trachomatis* act by inhibiting protein synthesis, growth and division of RBs, DNA-gyrase activity, or cell wall biosynthesis. Antibiotics used should be able to gain access to and exhibit activity in intracellular sites. The 72-hour life cycle and the asynchronous nature of chlamydial infection further require the maintenance of adequate antibiotic concentration in tissues. Table 167.2 summarizes treatment regimens for chlamydial infections. Antibiotic resistance has been described only rarely.

TABLE 167.2

Recommended Oral Treatment Regimens for *Chlamydia trachomatis* Infections

Condition	Treatment
PERINATAL INFECTIONS	
Inclusion conjunctivitis *or*	Erythromycin (50 mg/kg/day in 4 doses) for 14 days *or*
Pneumonia of infancy	Azithromycin (20 mg/kg/day in one dose) for 3 days
OCULOGENITAL INFECTIONS	
Children: <45 kg	Erythromycin (50 mg/kg/day in 4 doses) for 14 days
Children: ≥45 kg but <8 years old	Azithromycin (1 g in a single dose)
Children: ≥8 years old	Azithromycin (1 g) single dose Doxycycline (100 mg twice daily) for 7 days
Nonpregnant adolescents or adults	Doxycycline (100 mg twice daily) for 7 days *or*
	Azithromycin (1 g) single dose *or*
	Alternative regimen:
	Levofloxacin (500 mg 2 times daily) for 7 days *or*
	Ofloxacin (300 mg 2 times daily) for 7 days *or* Erythromycin base (500 mg 4 times daily) for 7 days *or*
	Erythromycin ethylsuccinate (800 mg 4 times daily) for 7 days
Pregnant adolescents or adults	Azithromycin (1 g) single dose *or* amoxicillin (500 mg 3 times daily) for 7 days
	Alternative regimen:
	Amoxicillin (500 mg 3 times daily for 7 days) *or* Erythromycin base (500 mg 4 times a day) for 7 days *or* Erythromycin base (250 mg 4 times daily) for 14 days *or*
	Erythromycin ethylsuccinate (800 mg 4 times daily) for 7 days *or*
	Erythromycin ethylsuccinate (400 mg 4 times daily) for 14 days
LYMPHOGRANULOMA VENEREUM	Aspiration of fluctuant buboes plus doxycycline (100 mg twice daily) for 21 days *plus* erythromycin base (500 mg 4 times daily) for 21 days
TRACHOMA	Azithromycin (20 mg/kg to max of 1 g) as a single dose to the case and all contacts

Data from Workowski KA, Bolan GA. Sexually transmitted diseases treatment guidelines, 2015. MMWR Recomm Rep 2015; 64(RR-03):1-137.

Perinatal Infection

Topical treatment of inclusion conjunctivitis is not recommended because local therapy does not eliminate nasopharyngeal carriage and subsequent risk for pneumonia or recurrent conjunctivitis. Conjunctivitis or pneumonia is treated with a macrolide orally. The efficacy of erythromycin therapy is approximately 80%; a second course may be required in some cases.[102] Erythromycin can have gastrointestinal side effects and interact with other drugs and has been associated with infantile hypertrophic pyloric stenosis (IHPS) in infants <6 weeks of age.[103] Azithromycin suspension was shown to be safe and effective for neonatal chlamydial conjunctivitis in one study.[104,105] The recommended dosage was 20 mg/kg/day for 3 days. A recent retrospective cohort study using the military health system database demonstrated an increased risk for IHPS after drug exposure in the first 14 days of life: after erythromycin (OR, 13.3; 95% CI, 6.80–25.9) and azithromycin (OR, 8.26; 95% CI, 2.62–26); and after exposure between 15 and 42 days of life: erythromycin (OR, 4.10; 95% CI, 1.69–9.91) and azithromycin (OR, 2.98; 95% CI, 1.24–7.20).[106] The risk for IHPS after treatment with other macrolides is unknown.

Prophylactic therapy of infants born to women known to have untreated chlamydial infection is not indicated because the efficacy of such prophylaxis is limited. Such infants should be monitored for signs of infection and to then ensure appropriate treatment.

Oculogenital Infection

Treatment for uncomplicated oculogenital infections in nonpregnant adolescents and adults is doxycycline for 7 days or azithromycin in a single dose.[107,108] Erythromycin is less efficacious than both azithromycin and doxycycline, and gastrointestinal side effects discourage adherence to treatment.

Sex partners should be evaluated, tested, and treated if they had sexual contact with the patient during the 60 days preceding either onset of the patient's symptoms or diagnosis of *Chlamydia*. The most recent sex partner should be treated even if the time of the last sexual contact was >60 days before diagnosis of the index case. Patients do not need to be retested for eradication after completing treatment with doxycycline or azithromycin unless symptoms persist or reinfection is suspected. A test of cure may be considered 3 weeks after completion of treatment with erythromycin. Testing at <3 weeks after completion of therapy to identify cases that did not respond to therapy may not be valid.[109]

Azithromycin is the recommended first choice for treatment of pregnant women, with amoxicillin as the alternative.[107] Doxycycline and ofloxacin are contraindicated in pregnant women. Azithromycin is prescribed widely during pregnancy and lactation and is excreted minimally in breast milk. The benefits of human milk feeding outweigh the risks associated with infant exposure to small amounts of azithromycin.

Lymphogranuloma Venereum

Recommended oral treatment for LGV is doxycycline for 21 days or erythromycin base for 21 days.[107] Fluctuant buboes should be aspirated through intact skin to prevent bubo rupture with formation of sinus tracts.

Trachoma

Trachoma control programs including screening and antibiotic treatment are conducted on a population level. However, on the occasion that an individual comes to attention with symptoms indicating trachoma, the individual should be examined and tested, and if trachoma is diagnosed the case and contacts should be treated with a single dose of azithromycin. Results of trials of mass treatment with single doses of azithromycin at the village level indicate that both infection and clinical disease are decreased markedly at 6 and 12 months later.[110–112]

Complications and Sequelae

Chlamydiae can persist in host cells in a quiescent state for extended periods. *C. trachomatis* has been implicated as a pathogen in 8% to 54% of women who have PID and has been associated with the long-term consequences of tubal infertility (17%), ectopic pregnancy (10%), or chronic pelvic pain (17%).[113] Pregnant women with untreated chlamydial infection are at risk for endometritis after delivery or induced abortions[114] and can experience adverse pregnancy outcomes such as premature rupture of membranes, prematurity,[33] and stillbirth.[77]

C. trachomatis infection and its complications account for serious morbidity and economic cost. In males, epididymitis, prostatitis, and reactive arthritis are the most common sequelae. Furthermore, untreated or incorrectly treated chlamydial conjunctivitis can result in chronic conjunctivitis that can develop alone or as part of Reiter syndrome, which includes urethritis, conjunctivitis, mucosal lesions, and reactive arthritis.

Prevention

Screening of high-risk patients for subclinical *C. trachomatis* infection is the most effective means of preventing disease and sequelae. Behavioral interventions (e.g., delaying intercourse, decreasing the number of sex partners, and using barrier method of contraception) should be pursued aggressively. Women with any of the following risk factors should be tested routinely for *Chlamydia*: mucopurulent cervicitis, sexually active and <20 years of age, >1 sex partner during the last 3 months, or inconsistent use of barrier contraception while in a nonmonogamous relationship.[107] Because of the frequency of repeated chlamydial infections within the first several months after treatment of an initial infection, more frequent (e.g., every 6 months) screening of asymptomatic sexually active adolescents may be necessary.[20] A cost-effectiveness study published in 1998 in women attending family planning clinics revealed that a strategy that combined use of PCR on cervical specimens in women receiving pelvic examinations and use of PCR testing of urine of women with no medical indication for a pelvic examination prevented the most cases of PID and provided the highest cost savings.[115]

Pregnant women should be screened and treated for *C. trachomatis* to prevent adverse pregnancy outcomes, chlamydial infection among infants, and maternal postnatal complications.[107] Mothers of infants who have *Chlamydia* and the male partners of these women should be evaluated, tested, and treated presumptively.

In neonates, ocular prophylaxis with topical erythromycin or tetracycline has reduced the incidence of gonococcal ophthalmia but does not appear to be effective against *C. trachomatis* and can mask infection at other sites.[116]

To combat trachoma, the World Health Organization has endorsed an integrated strategy known as SAFE: *S*urgery for people at immediate risk of blindness, *A*ntibiotic therapy to treat individual active cases and reduce the community reservoir of infection, *F*acial cleanliness and improved hygiene to reduce transmission, and *E*nvironmental improvements to elimination of living conditions that facilitate the maintenance and transmission of trachoma. This strategy has successfully eliminated trachoma in several countries, and global efforts are underway to eliminate blinding trachoma worldwide by 2020.[117]

Chlamydial EBs are extremely efficient invaders of mucosal epithelial cells, and because the replicating RB form resides within an intracellular inclusion, bacterial killing at this stage requires a cell-mediated immune response, with the primary effectors being interferon γ−secreting Th1 cells. Novel delivery methods and Th1-inducing adjuvants that induce strong mucosal T-lymphocyte immunity likely will be necessary for any effective chlamydial vaccine.[118] Attenuated *C. trachomatis* ocular strains devoid of plasmid have shown promise as a vaccine against trachoma in macaques.[119] Incorporation of molecular technology and increasing understanding of the host response to chlamydiae will aid development of vaccine candidates.

Chlamydia (Chlamydophila) psittaci (Psittacosis)

Preeta Krishnan Kutty

The Pathogen

Chlamydia psittaci (also known as *Chlamydophila psittaci*) is a gram-negative obligate intracellular zoonotic bacterium that causes both systemic infection and pneumonia, often referred to as *psittacosis* or *ornithosis* (Fig. 168.1).[1] Originally named *parrot fever* because of its association with psittacines (e.g., parrots, parakeets), psittacosis can be transmitted by virtually all domestic and wild birds.[2,3]

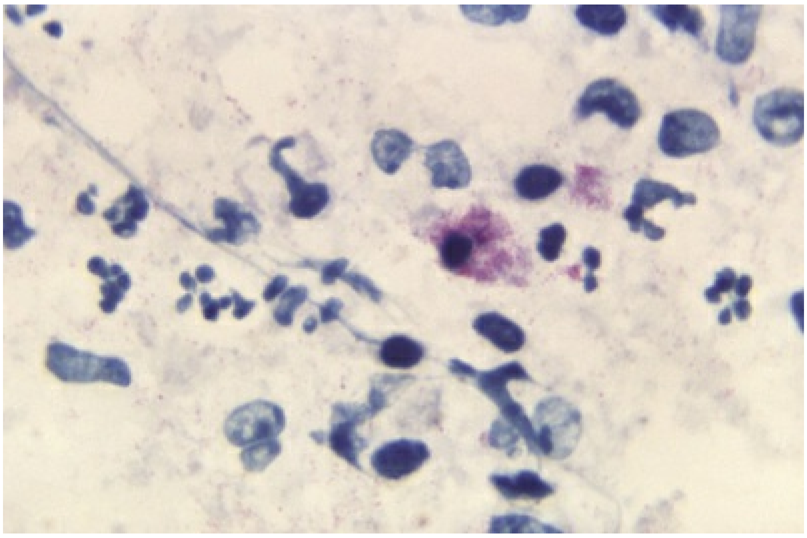

FIGURE 168.1 Photomicrograph of *Chlamydia psittaci*.
(Courtesy of D. Reese, Centers for Disease Control and Prevention.)

Epidemiology

Psittacosis was first described in 1879.[4] It became a nationally notifiable disease in the United States in 1944.[5] From 1992 through 2012, the Centers for Disease Control and Prevention (CDC) received 757 reports of psittacosis, with a decrease in reported incidence over the 20 years (Fig. 168.2). Overall, 9% of cases occurred in people younger than 20 years.[6] The low number of reported cases, especially pediatric cases, is likely an underestimate of the actual number of cases because of (1) lack of recognition by clinicians, (2) difficulties in diagnosis of infection, and (3) underreporting. As of 2008, psittacosis was reportable in all states except Connecticut and Texas.[7] Disease incidence does not vary by season.

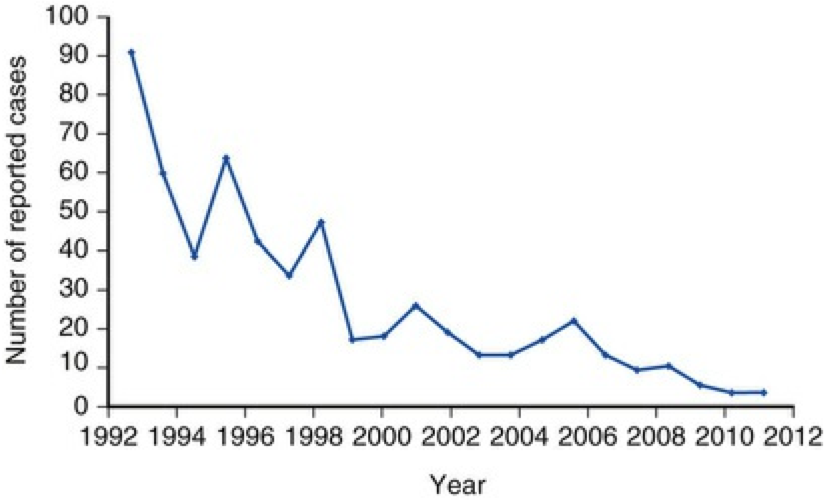

FIGURE 168.2 Cases of psittacosis reported to the Centers for Disease Control and Prevention, 1992 to 2012.

C. psittaci is transmitted through inhaled aerosols from the respiratory tract secretions, eye secretions, urine, or feces of infected birds.[1] Mouth-to-beak contact, handling of plumage, and lawn-mowing have been reported modes of exposure.[8] Illness can occur after even brief exposure to infected birds or their droppings. Most reported psittacosis cases have a known exposure to pet birds. However, outbreaks associated with domiciliary birds, wild birds, poultry processing, veterinary clinics, and aviaries have been described.[9–14] Infected birds can be asymptomatic or only mildly ill and can shed the organism for prolonged periods after recovery.[15] Because *C. psittaci* resists drying and can remain infectious in the environment for months, bird exposure may not be reported in some cases. Although biologically plausible, reports of person-to-person transmission are rare.[16–18] Confirmed and probable cases of psittacosis should be reported to the local or state health department to prevent further transmission.[7]

Clinical Manifestations

Psittacosis classically causes an "atypical" pneumonia. However, the acute disease manifestations can range from a mild, influenza-like illness to severe systemic disease[12,19] (Box 168.1), rarely fatal in humans if treated properly.[20,21] Symptoms generally develop after an incubation period of approximately 5 to 14 days but can occur up to 1 month after exposure.[12] Because signs and symptoms of C.

psittaci infection are similar to those caused by other community-acquired pneumonia pathogens (including *Mycoplasma pneumoniae, Chlamydophila pneumoniae, Coxiella burnetii,* and influenza virus), psittacosis should be considered in any child with pneumonia who has had close exposure to birds.[22,23]

Box 168.1

Clinical Manifestations of *Chlamydia (Chlamydophila) psittaci* Infection

Common

Fever

Chills

Weakness

Fatigue

Myalgia

Headache

Cough

Less Common

Temperature-pulse dissociation (fever without elevated pulse)

Splenomegaly

Rash

Rare

Myocarditis

Hepatitis

Arthritis

Keratoconjunctivitis

Encephalitis

Placental infection and fetal compromise (gestational psittacosis)

Laboratory Findings and Diagnostic Tests

Culture and isolation of *C. psittaci* rarely is undertaken outside research laboratories, largely owing to technical difficulties. Diagnosis usually is made by observing a fourfold or greater increase in antibody in a paired sera (acute and convalescent sera). In the absence of a clear exposure to birds, serologic testing should be interpreted cautiously because of the potential for cross-reactivity with other *Chlamydia* spp. Use of complement fixation is discouraged owing to its poor specificity. Microimmunofluorescence is generally more sensitive and specific than complement fixation; however, there is still some cross-reactivity with other chlamydiae.[1] Acute serum collection should occur as soon as possible after onset of clinical illness, with convalescent serum collection 2 to 4 weeks later. A real-time polymerase chain reaction assay for *C. psittaci* has been developed using respiratory specimens but is available only in specialized laboratories.[24–28] Information on availability of laboratory testing can be obtained from most state public health laboratories.[1]

Treatment

Tetracyclines are the drugs of choice for treating *C. psittaci* infections. In groups for whom tetracyclines are contraindicated (i.e., pregnant women and children younger than 8 years), macrolide antibiotics are considered the best alternative, although in vivo efficacy has not been determined.[29] Clinical response to therapy usually occurs within 48 to 72 hours; however, treatment should continue for 10 to 14 days after fever ceases in order to avoid relapse.[1] Tetracycline resistance has not been reported in *C. psittaci* but has been documented in other *Chlamydophila* spp.[30]

Key Points

Diagnosis and Management of *Chlamydia*

(Chlamydophila) psittaci Infection

Microbiology

- Obligate, intracellular, gram-negative coccobacilli
- Biphasic life cycle; includes two forms: elementary body (infective) and reticulate body (reproductive)

Epidemiology

- Reportable disease in the United States, with decline in incidence since 1990s
- Occurs sporadically and in outbreaks
- Transmitted through inhaled aerosols from the respiratory tract secretions, eye secretions, urine, or feces of infected birds
- Human-to-human transmission documented rarely

Diagnosis

- Clinical presentation and history of exposure to birds
- Paired serum showing more than fourfold increase in antibody titer using microimmunofluorescence
- Serologic cross-reactivity can occur; titer <1 : 128 should be interpreted with caution.
- Real-time polymerase chain reaction assay on respiratory specimens is available within specialized laboratories.

Treatment

- Tetracyclines are the drugs of choice.
- Macrolide antibiotics are considered the best alternative in patients for whom tetracyclines are contraindicated (e.g., pregnant women).

- Clinical response usually occurs within 48 to 72 hours.
- Treatment should continue for 10 to 14 days after fever ceases to avoid relapse.

Coxiella burnetii (Q Fever)

Gilbert J. Kersh

The Pathogen

Q fever (or "query" fever) is caused by the intracellular bacterium *Coxiella burnetii*, which belongs to the order Legionellaceae, family Coxiellaceae. *C. burnetii* primarily is a zoonotic pathogen. The organism can be present in high concentrations in the placenta and amniotic fluid of parturient animals and can be transmitted to humans through inhalation or direct contact.[1,2] *C. burnetii* is highly infectious to humans, with infection possible by inhalation of <10 organisms.[3,4] The organism survives and replicates in eukaryotic cells but also is remarkably long-lived in the environment, where it is resistant to environmental extremes and desiccation.[1,2] The organism is thus classified as a Category B bioterrorism agent. Human Q fever was made nationally reportable in 1999.[5]

Variation in the outer lipopolysaccharide of *C. burnetii* causes two antigenic phases: phase I is the pathogenic phase, and phase II is derived after laboratory passage and has low virulence. Persons with acute infection show primarily antibodies directed against phase II antigen, whereas people with chronic Q fever infections predominantly show a phase I antibody response.[6]

Epidemiology

Q fever is enzootic in domestic ruminants throughout the world, and human cases have a similar worldwide distribution.[1] Large outbreaks of Q fever have been reported from numerous geographic locations, including the United States, Australia, and Europe.[1] A particularly large series of outbreaks occurred in the Netherlands in 2007–2010, with >4000 Q fever cases documented.[7] Classically, outbreaks are linked to occupational exposure (farm or slaughterhouse workers) or research institutions that use pregnant livestock in research. Several outbreaks of Q fever have been documented among persons living downwind from infected livestock, strongly implicating windborne transmission.[8,9] Although sheep, cattle, and goats are most commonly implicated in the transmission of Q fever to humans, outbreaks also have been associated with other parturient animal species, including dogs and cats.[10,11] Ticks are known to harbor *C. burnetii* and can transmit infection in rare circumstances.[12,13] Consumption of unpasteurized dairy products also has been suggested as a possible means of transmission.[14]

In the United States, Q fever is widespread in cattle, sheep, and goats, with seroprevalence rates of antibodies to *C. burnetii* of 3%, 16%, and 42% in these animals, respectively.[15] In disease-endemic areas, contact with infected animals can result in sporadic cases or localized outbreaks of Q fever in humans. From 2008 through 2012, the average US annual reported incidence rate was 0.42 per million persons.[16] Because of difficulties in recognizing infection and establishing a diagnosis, the true incidence of infection likely is much higher. Seroprevalence surveys suggest that 3% of the general US population have antibodies to *C. burnetii*.[17] Seroprevalence is likely to be higher among persons with livestock contact; a survey of veterinarians found a seroprevalence of 22%.[18]

Q fever is considered to be a disease primarily of middle-aged adults rather than children, probably because of its strong occupational associations. The reported annual incidence of Q fever in children in the US is less than 0.05 cases per million persons (Fig. 169.1). From 2000 through 2012, a total of 47 cases of Q fever were reported in persons younger than 20 years in the US.[16] Studies examining age distribution in large outbreaks have shown that children less frequently develop symptomatic illness, even when exposures and seroconversion rates are similar to those observed in adults.[19] However, pediatric Q fever cases are recognized, especially in countries where Q fever is reported frequently.[20,21] A report of Q fever infections among children in Greece suggests that specific pediatric age groups (11–14 years of age) and risk factors (livestock contact, consumption of unpasteurized dairy products) may be associated with infection.[21]

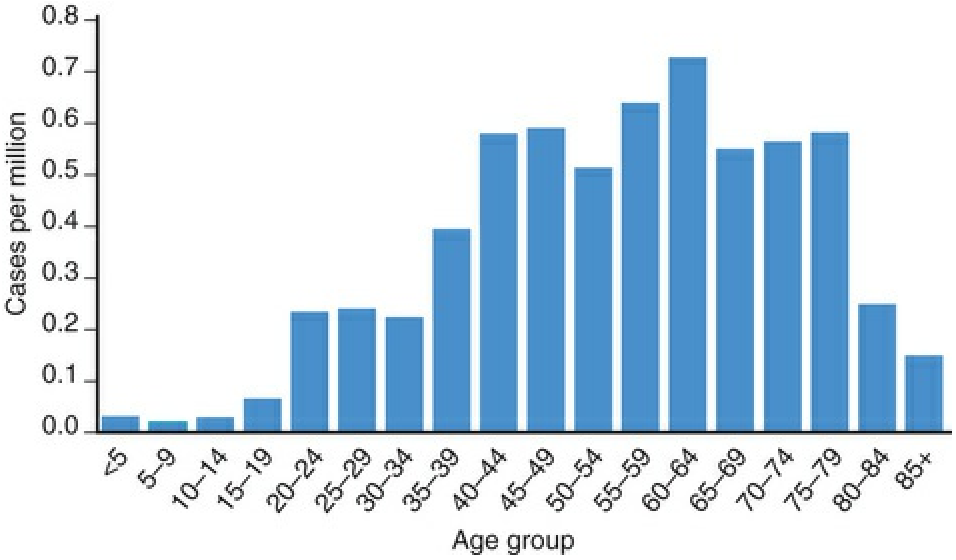

FIGURE 169.1 Cases of acute Q fever per million persons in the United States in specific age groups. The data cover the years 2008–2012. (From Dahlgren FS, McQuiston JH, Massung RF, et al. Q fever in the United States: summary of case reports from two national surveillance systems, 2000–2012. Am J Trop Med Hyg 2015;92:247–255.)

Clinical Manifestations

Outbreak investigations have suggested that >50% of adults and >80% of children exposed to *C. burnetii* can have asymptomatic infection.[19,22] Apparent infections can result in signs and symptoms ranging from mild to severe. Although acute infection may be self-limited, all recognized cases should be treated. Chronic forms of infection are more severe, can be life-threatening, and require long-term treatment.[1,2] Classic symptoms of acute respiratory Q fever in North America include sudden onset with fever, headache (often frontal), chills, general malaise, cough, anorexia, and myalgia. These symptoms should prompt the inclusion of Q fever in the differential diagnosis particularly in patients with a history of exposure to ruminants. However, the lack of direct animal contact should not preclude a clinical suspicion because airborne transmission of *C. burnetii* is possible.

Acute Q fever manifests 1 to 3 weeks after exposure, and symptoms in children usually are similar to those recognized in adults. Acute infection typically is a self-limited febrile illness or pneumonia.[1,2,23] In children, Q fever pneumonia may be characterized by a cough (up to 90% of cases) and radiographic changes that include bilateral infiltrates, atelectasis, and pleural effusion.[23] Respiratory failure and death are uncommon but can occur in patients with underlying conditions.[24] A review of 18 cases of Q fever in infancy listed fever of unknown origin as the most frequent clinical manifestation; pneumonia, convulsions, and malaise also were reported.[25] Common clinical signs among infants in the series included anorexia, cough, and diarrhea.[25] In a review of hospitalized children with Q fever in Spain, common symptoms included fever (92%), gastrointestinal tract symptoms (83%), hepatomegaly (67%), fatigue (50%), cough (50%), headache (42%), splenomegaly (25%), arthralgia (17%), and nuchal rigidity (8%).[19,26] In a review of pediatric Q fever cases in Australia, most experienced a clinical illness similar to illness observed in adults, and 14% reportedly experienced protracted symptoms of fatigue >3 months after acute infection.[20] More severe manifestations of acute disease include severe atypical pneumonia, hepatitis, myocarditis, pericarditis, rhabdomyolysis, or meningoencephalitis.[1,2,19,21,26–29] A case of hemolytic uremic syndrome has been reported.[30]

Chronic Q fever occurs months or years after the initial acute infection and can be difficult to diagnose because of its lack of a temporal association with specific exposures. Chronic infection is characterized by development of chronic hepatitis, osteomyelitis, infective endocarditis, or vascular infection.[1,2,19,27,31,32] Children with Q fever osteomyelitis may not show systemic illness but often experience recurrent episodes at multiple sites, which are poorly responsive to traditional treatment.[31] Children with a history of underlying heart valve disease or immunocompromising conditions may be at increased risk for developing chronic Q fever endocarditis, which manifests as culture-negative endocarditis.[19] Chronic Q fever endocarditis can be fatal, especially if it is not recognized and treated.

Laboratory Findings and Diagnosis

Abnormal laboratory findings in children with Q fever include elevation of serum hepatic enzymes, leukopenia or leukocytosis, and thrombocytopenia.[2,26] Because of the vague clinical signs associated with Q fever, most physicians rely on serologic tests for confirmation. Indirect immunofluorescent antibody assays are used most commonly. These tests can detect either phase I or phase II antibodies, which can help differentiate between acute and chronic infection.[6] In general, chronic infections are associated with a higher ratio of phase I to phase II antibodies than acute infections.[6]

Although considered the gold standard for diagnosis, serologic confirmation of Q fever infection can be difficult. Most serologic tests are based on detection of immunoglobulin G (IgG), which usually appears 9 to 14 days after onset of clinical signs.[6] Laboratory confirmation is complicated further by the persistence of elevated IgG titers for years after infection[33]; a single elevated IgG titer may not be strong evidence of recent infection. The presence of IgM antibodies is stronger evidence of recent infection; IgM antibodies appear as early as 4 days after symptom onset.

The most reliable method for diagnosis of Q fever is the laboratory testing of acute- and convalescent-phase serum samples. Paired serum samples that show a fourfold change in phase II IgM or IgG titer should be considered indicative of confirmed cases of Q fever for reporting purposes.[5] Patients with a clinically compatible illness who show a single elevated titer should be considered probable cases.[34] Chronic Q fever is confirmed in patients with a compatible clinical illness (e.g., endocarditis, vascular infection), whose phase I IgG titer is ≥1 : 1024.[34]

Demonstration of *C. burnetii* in blood or tissue samples through polymerase chain reaction (PCR), immunohistochemistry, or culture also can be used for diagnosis.[34] PCR on blood or serum is essential for diagnosis in the early stages of infection before antibody titers are detectable.[35] Immunohistochemistry and culture are useful on excised heart valve tissue for patients with endocarditis undergoing valve replacement surgery. Only biosafety-level 3 laboratories should attempt isolation and culture of the organism.[1]

Treatment

Because a definitive diagnosis of Q fever can be delayed, clinicians should provide empiric treatment based on a suspicion of Q fever. Although most cases of acute Q fever infection resolve without treatment, antibiotic treatment may shorten the length of clinical illness.[1,2,19] For treatment of acute Q fever in children of any age, doxycycline (2.2 mg/kg twice daily, with a maximum of 200 mg/day) should be administered for 14 days.[34] Studies suggest that this dosage and duration of doxycycline will have no appreciable effect on tooth color.[36,37] Alternative antibiotics that might be considered in milder cases include trimethoprim-sulfamethoxazole or rifampin.[19]

Treatment of chronic Q fever requires aggressive, long-term antibiotic therapy. In adults, combination therapy consisting of oral doxycycline and hydroxychloroquine for at least 18 months usually is required.[19,38] Even with long-term therapy, relapse can occur after cessation of antibiotic treatment. An infectious diseases specialist should be consulted regarding treatment and serologic follow-up of chronic Q fever in children.

Special Considerations

Children with chronic immunosuppressive conditions may be at increased risk for Q fever infection. A fatal case of Q fever pneumonia is reported in a child with chronic granulomatous disease,[24] and patients with congenital heart defects or chronic immunosuppressive conditions may be predisposed to develop Q fever endocarditis.[19] Patients with preexisting valvular heart disease should have careful consideration and serologic monitoring to optimize early detection and rapid treatment of chronic *C. burnetii* infection.

Case reports have associated *C. burnetii* infection during pregnancy with abortion or premature delivery, and *C. burnetii* has been isolated from the placenta and milk of infected mothers.[19,39,40] Infected women may pose a risk for infection to healthcare providers during delivery because of aerosolization of infectious material.[40] Pregnant women who are diagnosed with Q fever should be treated with trimethoprim-sulfamethoxazole up to 32 weeks' gestation, and followed serologically to evaluate possible progression to chronic infection.[19,41]

Prevention

Children can be protected by minimizing contact with parturient and newborn animals, especially livestock, including sheep, goats, and cattle. Adults who come in contact with parturient or newborn animals should take care to minimize their own contact with children until they can shower and wash potentially contaminated clothing.[11] Because dairy products sometimes have been implicated as a means of transmission, children should be allowed to consume only milk and dairy products that have been boiled or pasteurized. A Q fever vaccine is not currently licensed for use in the US, but a licensed vaccine is available in Australia. Its use generally is limited to persons with high-risk occupations, such as abattoir workers and laboratory scientists who work with *C. burnetti*.[1,2,42]

Key Points

Diagnosis and Management of *Coxiella burnetii* Infection (Q Fever)

Microbiology

- Obligate intracellular, gram-negative γ-proteobacterium
- Grows in embryonated eggs, mice, guinea pigs, or tissue culture of host cells

Epidemiology

- Zoonotic pathogen with worldwide distribution
- Cases and outbreaks usually are associated with exposure to domestic ruminants.
- Occupational exposure to infected animals is a significant risk

factor.

- Seroprevalence in US persons is 3%.

- Disease likely is underreported owing to nonspecific flu-like symptoms.

Clinical Manifestations and Diagnosis

- Acute form Q fever usually manifests 1 to 3 weeks after exposure with flu-like symptoms, sometimes also with pneumonia and/or hepatitis.

- Chronic Q fever can develop many months after infection.

- Chronic infection can result in culture-negative endocarditis (possibly requiring valve replacement) or osteomyelitis.

- Detection of fourfold rise in phase II immunoglobulin G serum antibody titer is the most common method of diagnosis.

- Antibody titer usually does not increase until at least 2 weeks after symptom onset.

- Polymerase chain reaction assay can detect *Coxiella burnetii* in blood or serum samples during first 2 weeks of symptoms.

Treatment

- Doxycycline (2.2 mg/kg twice a day, maximum of 200 mg/day) is the optimal treatment.

- No significant drug resistance is reported.

- Acute infection: 14-day course of antibiotic

- Chronic infection: ≥18 months of therapy may be needed; relapse is not uncommon.

Family Anaplasmataceae (*Anaplasmosis, Ehrlichiosis, Neorickettsiosis,* and *Neoehrlichiosis*)

William L. Nicholson

Description of the Pathogens

The family Anaplasmataceae is classified in the order Rickettsiales and currently contains five genera and two candidate genera of obligate intracellular bacteria. Four of the genera contain members that are known to infect humans: *Anaplasma, Ehrlichia, Neorickettsia,* and "*Candidatus* Neoehrlichia." These zoonotic bacteria are transmitted by invertebrate vectors and can cause potentially life-threatening diseases in humans and animals. Their natural cycles are maintained through vector transmission among wildlife or domestic animals. Five species in the genus *Ehrlichia* and four species in the genus *Anaplasma* are documented as causes of human disease, and multiple species have been reported from children and adolescent patients worldwide (Table 170.1). Globally, thousands of human cases due to Anaplasmataceae are reported each year, particularly in the United States. The dominant species responsible for disease in the US are *Ehrlichia chaffeensis, E. ewingii*, *E. muris eauclairensis*, and *Anaplasma phagocytophilum*. As new species are characterized, it is likely that additional Anaplasmataceae capable of causing human disease may be discovered in the future.

TABLE 170.1

Characteristics of Bacterial Species in the Family *Anaplasmataceae* That May Infect Humans

Species[a]	Geographic Distribution	Primary Target Host Cell	Primary Invertebrate Vector
Ehrlichia chaffeensis	North America (some evidence for infection in S. America, Africa, and Asia)	Monocytes, macrophages	*Amblyomma americanum*
Ehrlichia ewingii	North America (some evidence for infection in Africa and Asia)	Granulocytes	*Amblyomma americanum*
Ehrlichia muris muris	Asia (PCR-positive cases from Far East Russia)	Undetermined (perhaps monocytes)	*Ixodes persulcatus*
Ehrlichia muris eauclairensis[b]	North America (found only in Minnesota and Wisconsin)	Undetermined (may be found in endothelial cells of infected mice)	*Ixodes scapularis*
Ehrlichia canis	Worldwide (limited human cases in Venezuela)	Monocytes, macrophages	*Rhipicephalus sanguineus*
Ehrlichia ruminantium	Africa, North America (Panola Mountain strain in US) (uncommon)	Endothelial cells	Several *Amblyomma* spp. (*A. americanum* in US)
Anaplasma phagocytophilum	Worldwide	Granulocytes	*Ixodes scapularis, I. pacificus* (North America), *Ixodes ricinus* (Europe), *Ixodes persulcatus* (Asia)
Anaplasma platys	Worldwide (limited human cases reported from Venezuela, US)	Platelets	*Rhipicephalus sanguineus* (suspected)
Anaplasma ovis	Europe, Asia, Africa, North America (human cases in	Erythrocytes	*Rhipicephalus bursa, R. sanguineus* (suspected); *Dermacentor andersoni* (US)

	Cyprus and Iran)		
"Anaplasma capra"[c]	China (multiple human cases)	Undetermined (bone marrow precursor cells or endothelial cells suspected)	*Ixodes persulcatus*
Neorickettsia sennetsu	South-East Asia (uncommon)	Monocytes, macrophages	Trematodes (transmission is by ingestion of fish infested with flukes infected with neorickettsiae)
"*Candidatus* Neoehrlichia mikurensis"[d]	Europe, Asia (multiple human cases), Africa (one human case)	Endothelial cells (seen in infected animals, but not yet shown in humans)	*Ixodes ricinus* (Europe), *Ixodes persulcatus* (Asia)

[a] Bold indicates documented cases in the pediatric population.

[b] Formerly designated the *Ehrlichia muris*–like agent, but has now been recognized as a subspecies of *E. muris*.

[c] This species name has been proposed for the agent cultured from humans and animals, but a published description following the rules of the International Code of Nomenclature of Bacteria will be required to formally name the species.

[d] This taxon is biologically and genetically distinct. Although the candidate genus and species have been proposed and used in the literature, a formal description published according to the rules of the International Code of Nomenclature of Bacteria will be required for recognition of these designations as valid names.

Data from References 7, 19–33.

Ehrlichia and *Anaplasma* species are small (0.5–1.5 μm) gram-negative cocci.[1] The genomes of these organisms are relatively small, with a size of 1.18 Mb for *E. chaffeensis* and 1.47 Mb for *A. phagocytophilum*.[2] After attachment to membrane receptors on the surface of target cells and subsequent induction of phagocytosis, the organisms multiply in endosomes that fail to develop into mature phagocytic or lysosomal vacuoles. Organisms reside within the cell cytoplasm of infected cells (monocytes, granulocytes, macrophages, erythrocytes, platelets, and endothelial cells, depending on the species). Organisms replicate within membrane-bound vesicles to form microcolonies known as morulae.[3] The morphologic features of morulae vary among the species in size, number of individual organisms, and presence of a fibrillar matrix (Fig. 170.1). Individual morulae can contain few to many bacteria, which are released into the extracellular space after cell lysis or by exocytosis after fusion of the vacuole membrane with the plasma membrane. *Ehrlichia* spp. can spread to uninfected cells by concentration in filopodia in early infection and by host cell membrane rupture in late infection. *Anaplasma* are released by host cell lysis without loss of host cell cytoplasm.[3,4] *Neorickettsia sennetsu* is found in monocytic cells of blood and lymph nodes, whereas the target cell of "*Candidatus* Neoehrlichia mikurensis" is not yet known for humans. It has been found in endothelial cells of infected rodents.

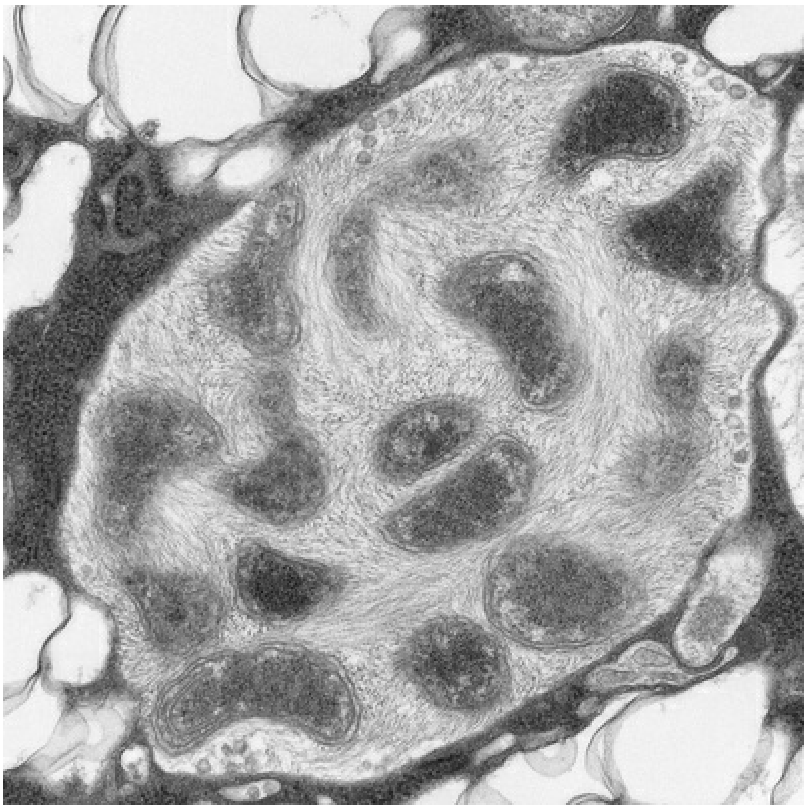

FIGURE 170.1 Electron micrograph of *Ehrlichia muris eauclairensis* morula within an infected endothelial cell (RF/6A). Note the fibrillar material among the pleomorphic organisms contained in the vacuole.

Ehrlichia and *Anaplasma* spp. have developed adaptive mechanisms to subvert the host cell response and increase their survival.[3,5] Immune response of the host appears to be responsible for the pathology seen in infected patients, and cytokine and chemokine production by infected tissues may lead to more severe damage. Perivascular inflammatory infiltrates become apparent in many organs, and morulae can be visualized within the leukocyte populations present in these infiltrates. Mechanisms of many of the hematologic and biochemical perturbations (e.g., cytopenia and abnormal serum hepatic enzyme levels) are not completely clear.[6] It is noteworthy that these infections do not usually cause the vasculitis or endothelial damage characteristic of other rickettsial diseases, such as Rocky Mountain spotted fever.

Epidemiology

Ecologically, the species of Anaplasmataceae are usually maintained in wild or domestic mammalian species and are transmitted within that system and to humans though invertebrate vectors, most often through the bite of a hard tick (Acari: Ixodidae).[7,8] The pathogens are distributed within the geographic ranges of their primary tick vectors.

The members of the Anaplasmataceae can infect persons of all ages but are more frequently recognized in older adults. More than half of patients are hospitalized, and infections can result in life-threatening illness.[9] The epidemiology of infections in children is derived from case reports and case series in the literature.[10–15] *E. chaffeensis* accounts for most Anaplasmataceae infections seen in the pediatric population. In the most recent surveillance summary, the case fatality rate was highest in children younger than 5 years and in adults 70 years and older.[16] Active surveillance for *A. phagocytophilum* (also called human granulocytic anaplasmosis) indicates that the age-specific incidence is notably low in persons younger than 18 years and is highest in adults older than 50 years. Reasons for low case numbers in younger patients remain unclear, and the frequency of asymptomatic infection in children is unknown. Seroprevalence studies using generally accepted cutoff titers suggest that about 5.3% of children 19 years or younger in an endemic area of New York had antibodies to *A. phagocytophilum*,[17] and another study indicated that 13% of children aged 17 years or younger in the south-central and southeastern US had antibodies to *E. chaffeensis*.[18]

Infections by the Anaplasmataceae occur throughout the world, yet specific pathogens occur in certain regions or countries[7,19–33] (see Table 170.1). *A. phagocytophilum* has been documented in many countries, whereas *E. chaffeensis* is thought to occur primarily in the US. *E. chaffeensis* or antigenically similar organisms (some supported by molecular evidence) have been detected in other countries, suggesting a wider range than appreciated currently.[34] *N. sennetsu* generally is limited to South East Asia and has more recently re-emerged in Laos.[22] Despite the fact that "*Candidatus* Neoehrlichia mikurensis" is widespread in rodents and ticks in Europe and Asia, human cases have not been numerous, and childhood infection has not been documented.[33,34] Further study utilizing culture and multiple molecular targets for Anaplasmataceae infections will enhance our knowledge of emerging pathogens and help determine their threat to public health.

In the US, national passive surveillance found a fourfold increase in the number of ehrlichiosis cases reported from 2008–2012 compared with 2000.[16] From 2008–2012, 4613 cases of *E. chaffeensis* were recorded. The incidence rate was 3.2 cases/million person-years, with a 57% hospitalization rate and 1% case fatality rate. The highest case fatality rate (4%) was seen in children younger than 5 years. During this same period, 55 cases of *E. ewingii* were reported to national surveillance. The incidence rate was 0.04 cases/million person-years, with a 77% hospitalization rate. No death was recorded. Cases occurred across the southeastern and south-central US and in New Jersey and Indiana.[16,35] Although in previous studies infection primarily affected patients with altered immune status, cases reported more recently have occurred in previously healthy persons.

The US cases of anaplasmosis also increased in national surveillance system reports.[36] From 2008–2012, a total of 8896 cases of *A. phagocytophilum* infection were reported, with an overall incidence of 6.3 cases/million person-years. Cases were reported from 38 states, and the highest incidence was seen in Minnesota (97 cases/million person-years), Wisconsin (79), and Rhode Island (51). The hospitalization rate was 31%, with a case fatality rate of 0.3%. Increasing age was associated with incidence, hospitalization, and case fatality rates.

From 2008–2012, a total of 726 cases of ehrlichiosis or anaplasmosis for which the specific etiology could not be determined based on available test results also were reported through national passive surveillance.[37] When active case finding is conducted, both ehrlichiosis and anaplasmosis show incidences a magnitude higher than national passive surveillance.

Human ehrlichioses and anaplasmosis share certain epidemiologic features. In addition to being reported most commonly in adults, cases are reported most frequently in males.[6] Approximately 60% of the recorded pediatric cases have occurred in boys.[10–12] Although cases can occur throughout the year, the peak seasonal incidence of disease is in May through August.[9,38–40] Although generally a sporadic disease, clusters of cases have occurred during recreational activities and occupational exposure. Certain populations may be disproportionately affected by rickettsial diseases. It has been shown that American Indians in the US had a higher incidence rate of infection than other races.[41] Although ehrlichiosis and anaplasmosis generally increase with age, American Indian cases had more cases in the lower age groups. Most American Indian cases were reported from geographic regions endemic for ehrlichiosis, which may reflect increased exposure.

The endemic region for specific diseases can be reasonably approximated by the geographic distribution of each agent's primary tick vector.[34,42] The pathogens are maintained in a variety of domestic and wildlife animal hosts by tick bite transmission. Infections caused by *E. chaffeensis* and *E. ewingii* are associated with the bite of the lone star tick, *Amblyomma americanum*.[34,40,42] This tick is primarily distributed across central Texas and eastern Oklahoma, eastward throughout the southeastern US, and northerly along the Atlantic coastal plain into New England. The greatest number of cases of *E. chaffeensis* ehrlichiosis and those caused by *E. ewingii* have been reported from the southeastern and south central US.[16] The recognized geographic range of *A. americanum* is expanding, suggesting that the area of risk for ehrlichial pathogens transmitted by this vector should be considered dynamic.[42,43] Most anaplasmosis cases have occurred in the north central and northeastern states, particularly New York, Connecticut, Minnesota, and Wisconsin.[36,39,44] The principal tick vector is the blacklegged tick, *Ixodes scapularis,* the same tick that transmits *Borrelia burgdorferi*.[42] This tick also is expanding its range, and more states reported anaplasmosis cases from 2008–2012 compared with previous years.[36,45] In the western US, *Ixodes pacificus* is the main vector of *A. phagocytophilum* to humans and animals.[42,44] In Europe, *Ixodes ricinus* has been incriminated in Europe, while *Ixodes persulcatus* is the primary vector in Asia.[44]

Ticks in the genus *Ixodes* can transmit several other pathogens, including *Babesia* spp., flaviviruses, and *B. burgdorferi.* Dual infections with *A. phagocytophilum* and *B. burgdorferi* have been reported.[46] In some children, the concurrent presence of anaplasmosis and Lyme disease has resulted in more severe disease.[47]

Other Anaplasmataceae.

E. muris eauclairensis recently has been recognized in Minnesota and Wisconsin.[25] More than 70 cases have been reported from residents or travelers to these two states. The epidemiology is not fully understood, but evidence suggests that *E. muris eauclairensis* can be found in white-footed mice and *I. scapularis* ticks at low levels. There are at least two polymerase chain reaction (PCR)-confirmed and 84 serologically diagnosed cases attributed to *E. muris muris* infection in the Perm region of Russia, whereas Japanese investigators reported a 1.1% seroprevalence of antibodies against *E. muris muris* among Tokyo residents.[26,29]

"*Candidatus* Neoehrlichia mikurensis" has been reported in elderly patients in Europe and Asia, yet pediatric cases have not been reported. Most patients were immunocompromised, and a majority were asplenic.[33,34] *Neorickettsia sennetsu* infection, also known as sennetus or glandular fever, is not common, with <100 reported cases in Southeast Asia since its first description in 1954.[22] The pathogen is thought to be transmitted by ingestion of raw or improperly cooked fish. The fish are infested with digenean trematodes (flatworms) that are, in turn, infected by the neorickettsiae. Other species (see Table 170.1) have been associated with human disease, but further investigation is needed to learn more about these emerging pathogens.

Clinical Manifestations

Children and adults come to attention with fever, malaise, headache, and myalgia. Laboratory abnormalities include leukopenia, thrombocytopenia, and increased serum hepatic transaminase levels. These early clinical features may resemble other infectious and noninfectious diseases. A high level of suspicion is important, particularly when obtaining a complete epidemiologic and travel history. Outdoor activities (occupational or recreational) can increase the risk for tick bite. Patients may not recall tick bites because of the small size of ticks and the fact that the tick is not often attached at presentation. Clusters of ehrlichiosis or anaplasmosis can occur geographically or temporally; asking about illness in associates or family can be helpful. History of travel within the US or to other countries will provide valuable clues to the possible etiology of suspected imported Anaplasmataceae infection (see Table 170.1).

The incubation period typically is between 5 to 21 days after a recognized tick bite.[39] Many parents and children (55% to 85%) recall a tick bite several days to weeks before the illness.[10,12,13] Common symptoms in children include fever, myalgia, and headache. Additional clinical features include anorexia, nausea or vomiting, and less frequently, hepatomegaly or spenomegaly.[12,42,46,48] In adults with *E. chaffeensis* infections, rash is seen in only about 25%, yet rash occurs in about 66% of children.[6,12,42] Fewer than 10% of patients infected by *A. phagocytophilum* exhibit a rash.[39,42] When present, rash typically involves the trunk (sparing the hands and feet) and can appear macular, papular, maculopapular, or occasionally petechial. Gastrointestinal tract symptoms, including nausea, vomiting, anorexia, and diarrhea, are observed in approximately 60% of children with ehrlichiosis, slightly greater than that reported in adults with *E. chaffeensis* infection.[12,42] Adults with anaplasmosis have gastrointestinal tract symptoms less frequently (<40%).[42,44]

Moderate to severe headache is a common feature regardless of etiologic agent; however, encephalitis or meningitis is most commonly reported with *E. chaffeensis*.[6] Long-term neurologic sequelae, including bilateral footdrop, speech impairment, and diminished reading and fine motor ability, have been described in children after severe disease.[6,12,13]

Infections can result in severe pulmonary disease and may be a cause of acute respiratory distress syndrome in adults or children.[6,13] Intubation and mechanical ventilation have been required for severe cases of *E. chaffeensis* ehrlichiosis.[12,13,49] As in adults, the most severe disease in children is associated with infection by *E. chaffeensis.* Immunosuppressive conditions, including chemotherapy and organ transplantation, may predispose children to more severe disease by *E. chaffeensis.*[13,50]

Presumably, the same or similar conditions predispose children to infection by *E. ewingii*. The first report of *E. ewingii* disease was in an 11-year-old boy receiving immunosuppressive therapy after kidney transplantation, and there have been recent case reports of severe *E. ewingii* infections in children with acute lymphoblastic leukemia and sickle cell disease.[13,14,51,52]

Opportunistic infections may occur in patients as a result of alterations in neutrophil and $CD4^+$ lymphocyte function.[7] Disseminated candidiasis, invasive pulmonary aspergillosis, *Cryptococcus neoformans* pneumonia, herpes simplex, and cytomegalovirus infections have been noted.[39,42,53] Reinfection of the same patient with *E. chaffeensis* has been reported and reinfection with *A. phagocytophilum* has been documented.[54,55]

Other Anaplasmataceae.

Frequent symptoms of neoehrlichiosis included fever, localized pain afflicting muscles or joints, vascular and thromboembolic events, transitory ischemic attacks, pulmonary embolism, and arterial aneurysm.[33] *Neorickettsia sennetsu* infection is characterized by fever, weakness, anorexia, and lymphadenopathy.[22]

Laboratory Findings and Diagnostic Tests

Differential diagnosis for Anaplasmataceae infections can be difficult because of the broad spectrum of clinical features. Early in the illness, the nonspecific findings of fever, headache, myalgia, nausea, and malaise can be mistaken for various viral syndromes, upper respiratory tract illness, septicemia, urinary tract infection, or gastroenteritis. A history of a tick bite is helpful in diagnosis of tick-borne illness, but clinical features may be similar to other tick-transmitted pathogens.[42]

Leukopenia (<4000 white blood cells/mm^3), thrombocytopenia (<150,000 platelets/mm^3), and elevations in liver transaminase levels (aspartate aminotransferase >55 U/L) characteristically develop in patients of all ages early in the course of the illness. These laboratory findings provide early presumptive clues to the diagnosis of Anaplasmataceae infection regardless of the specific agent.[12,13,42] Leukopenia occurs with both *E. chaffeensis* and *A. phagocytophilum* infection, with the nadir typically between 1000 and 4000/mm^3. Lymphopenia is common in patients with ehrlichiosis and anaplasmosis, and neutropenia is reported in adults with anaplasmosis.[42] Thrombocytopenia is reported in >70% of patients, with platelet counts generally between 50,000 and 150,000/mm^3. Anemia is reported in about one third of children with *E. chaffeensis* infection. The bone marrow of cytopenic patients usually is normocellular or hypercellular, suggesting that the leukopenia and thrombocytopenia could be due to peripheral sequestration or destruction.[6]

Mildly or moderately elevated levels of serum transaminases occur in most children infected by *E. chaffeensis*.[12,13,39,42] Alkaline phosphatase levels are less affected. Electrolyte abnormalities, particularly mild to moderate hyponatremia, are noted frequently in children and adults with severe disease.[11,12,42]

Cerebrospinal fluid (CSF) pleocytosis, elevated protein levels, or both most often are reported in patients with *E. chaffeensis* ehrlichiosis, as are episodes of confusion, disorientation, or delirium.[6] Morulae of *E. chaffeensis* have been identified in mononuclear cells in the CSF, and the organism has been isolated from the CSF of patients with ehrlichiosis.[42,56]

Other Anaplasmataceae.

General laboratory findings for neoehrlichiosis showed leukocytosis with neutrophilia, anemia, and elevated C-reactive protein levels. Peripheral blood smears can show atypical lymphocytes.

Diagnostic Testing

Targeted serologic and molecular laboratory methods can be used to confirm the diagnosis of ehrlichiosis or anaplasmosis, and many tests are available from commercial laboratories. More specialized testing may be available through state and national public health laboratories, specialized reference laboratories, or academic research centers. Diagnostic methods include serologic tests to measure specific antibody titers, detection of DNA by PCR assays of blood or CSF, detection of morulae in peripheral blood or CSF leukocytes, direct detection of ehrlichiae in tissue samples by immunohistochemistry, and isolation of the bacteria from clinical specimens.[9,42,57]

Indirect immunofluorescence can be used to detect *E. chaffeensis* or *A. phagocytophilum* immunoglobulin M (IgM) or IgG antibodies in serum or plasma. There are no serologic tests for *E. ewingii*. Specific serologic testing for the less common Anaplasmataceae affecting humans is limited to several commercial or research laboratories. A fourfold rise in IgG antibody titer between acute-phase (at healthcare presentation) and convalescent-phase (2–4 weeks later) serum samples can confirm the diagnosis in a patient with acute illness. Immunofluorescence assay tests to detect IgG and IgM antibodies frequently are negative in the first week of illness, providing limited diagnostic assistance, and do not exclude Anaplasmataceae infections. IgM titers can remain elevated for lengthy periods after treatment and resolution of disease. Antibodies reactive with other species can be seen in 10% to 30% of patients' sera and may be due to cross-reactive epitopes or with separate exposure events. However, antibodies cross-reactive with *E. chaffeensis* antigens can be useful in diagnosing some cases of *E. ewingii* infection.[42,51]

Identification of intraleukocytic morulae in peripheral blood, CSF, or bone marrow aspirate preparations stained with an eosin azure–type stain (e.g., Wright-Giemsa, Diff-Quik) may be used for presumptive diagnosis (Fig. 170.2).[56] Artifacts, toxic granules, and overlying platelets can sometimes be misinterpreted as morulae. Morulae are identified in leukocytes from patients with anaplasmosis (25%–75%) more often than from those with ehrlichiosis (~25%).[42,58]

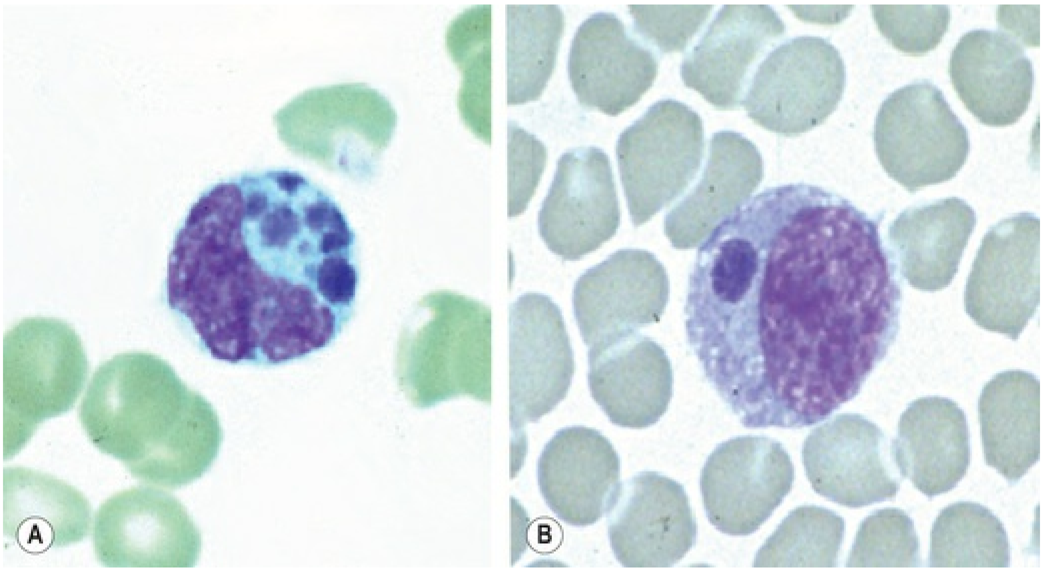

FIGURE 170.2 (A and B) Morulae of *Ehrlichia chaffeensis* as seen on Wright stain of mononuclear cells in the peripheral blood of patients with ehrlichiosis.

Molecular methods of laboratory diagnosis have greatly enhanced the detection and specific identification of rickettsial pathogens.[42,57,59] Although proven very useful for Anaplasmataceae infections, PCR also is the primary means by which *E. muris eauclairensis* and *E. ewingii* infections are identified in the US.[16,25,37] Positive results can be obtained from acute-phase whole blood samples before specific antibodies are detectable.[58] PCR is most sensitive during early infection (0–4 days) and is significantly less sensitive as the disease progresses.[60] Detectability by PCR declines rapidly after the first 24–48 hours of doxycycline treatment.

Cultivation of the microorganisms in a variety of susceptible cell lines provides a valuable means of diagnosis; however, this approach requires appropriate laboratory facilities and trained staff. Appropriate samples include blood, buffy coat, separated leukocytes, CSF, or other autopsy tissue samples, and primary isolation can take several days up to several weeks.[61,62] The sensitivity of other laboratory procedures compared with isolation has been investigated in only a few circumstances because isolation of these organisms is seldom attempted in clinical laboratories.[42] Cultivation has not yet been accomplished for *E. ewingii* or “*Candidatus* Neoehrlichia” infections.

Treatment

Anaplasmataceae infections respond well to appropriate antibiotic treatment.[9,42,63] When any rickettsial disease is suspected, appropriate antibiotic treatment should be initiated before laboratory results are available. Delayed treatment can increase rate of transfer into intensive care, increase duration of hospitalization, and increase length of illness.[64] Doxycycline is the drug of choice for adults and children of *all ages* infected with any Anaplasmataceae species.[13,39] For children, 2.2 mg/kg administered orally or intravenously every 12 hours is recommended. For older children and adults, the maximal (adult) dose is 100 mg administered orally or intravenously every 12 hours. Most patients can be treated with oral therapy, but severely ill patients or patients unable to tolerate oral medications are given doxycycline parenterally. Treatment length is variable, but typically is 7 to 14 days (at least 3 days after defervescence). Doxycycline therapy for 2 weeks may be required in patients coinfected with *A. phagocytophilum* and *B. burgdorferi* (Lyme disease).[42] The reluctance to treat children younger than 8 years with doxycycline generally is unfounded. Multiple studies have shown that short-term use of doxycycline, as is used for rickettsial infections, is safe and does not cause discoloration of teeth.[9,63,65]

With appropriate therapy, most patients defervesce within 24 to 48 hours. Indeed, failure to respond to a tetracycline antibiotic within the first 3 days should suggest possible infection with a nonrickettsial agent. Other clinical manifestations generally subside over the next 2 weeks, and patients recover completely. Occasionally, headaches, generalized weakness, and malaise can persist for several weeks after recovery from the acute febrile illness.

Special Considerations

Alternative treatment or prolonged treatment of infections is warranted only in rare circumstances. Alternate drugs have been used with limited numbers of patients. Chloramphenicol appears ineffective against *E. chaffeensis* when tested in cell culture systems, and treatment failure has been reported with this drug in some patients, including death in one child.[9,11,42]

Antibiotics used frequently for empiric treatment of bacterial infections in febrile patients (e.g., β-lactams, macrolides, aminoglycosides, and fluoroquinolones) are ineffective in treating Anaplasmataceae infection. Although levofloxacin has in vitro activity, it appears only to inhibit organisms, and infection recrudesces when drug is discontinued. Additionally, anecdotal evidence suggests that sulfa-containing antimicrobial agents may increase the severity of the disease. Descriptions of pediatric patients with severe or fatal infections include reports of children to whom sulfonamides were administered for a week or longer before the disease was diagnosed correctly.[49,53,66] It remains unclear whether use of sulfa drugs resulted in delayed diagnosis or exacerbation of infection.

Rifampin may be a suitable drug for use in patients with allergies, gastric intolerance, or phototoxic hypersensitivity to doxycycline. Limited numbers of *A. phagocytophilum* infections have been successfully treated with rifampin during pregnancy.[9,67–70] Healthy uninfected infants were delivered after treatment of the pregnant mothers at 17, 25, and 39 weeks' gestation. Rifampin has been used at a dose of 10 mg/kg given twice daily as single-agent therapy in two children with acute human granulocytic anaplasmosis.[68] Rifampin has been successfully used for treatment of *E. chaffeensis* infection in one adult patient.[69]

Prevention

No vaccine for any member of the Anaplasmataceae is available currently for humans, thus prevention of exposure through tick bite prevention is essential. Prevention of tick bites and avoidance of tick-infested habitats are key to preventing ehrlichiosis, anaplasmosis, and other tick-borne infections. Children returning from outdoor activities in tick-infested habitats should be inspected carefully for crawling or attached ticks. Appropriate use of approved tick repellents on skin or clothing is safe and effective in preventing tick bite, but adherence to the product label is important to reduce possible adverse effects in children. Daily body examinations for attached ticks (tick checks) are useful as prompt discovery and removal of recently attached ticks lessen the risk of infection; ticks may require 24 to 48 hours of attachment to a host before the bacteria can be transmitted.[42] Prophylactic administration of doxycycline after a tick bite is not indicated because the overall risk for infection is low, even when tick infection is documented.

Key Points

Diagnosis and Management of Anaplasmosis and Ehrlichiosis

Microbiology and Vectors of *Anaplasma* and *Ehrlichia* Species in the United States

- Anaplasmosis worldwide is caused by the bacterium *Anaplasma phagocytophilum*.

- The blacklegged tick (*Ixodes scapularis)* is the vector to humans in New England and the north central US; the western blacklegged tick (*Ixodes pacificus)* is the vector in northern California.

- Ehrlichiosis is caused by three bacteria in the US: *Ehrlichia chaffeensis, E. ewingii,* and *E. muris eauclairensis*.

- The principal vector of *E. chaffeensis* and *E. ewingii* is the lone star tick *(Amblyomma americanum);* the tick vector of *E. muris eauclairensis* is thought to be *Ixodes scapularis*.

Anaplasmataceae Outside the United States

- Various species of both *Anaplasma* and *Ehrlichia* cause infection in humans globally, but their public health impact is unclear.

- Neoehrlichiosis is an emerging pathogen of humans in Europe and Asia, is caused by "*Candidatus* Neoehrlichia mikurensis," and is transmitted by various *Ixodes* spp. of ticks.

- Neorickettsiosis is a re-emerging illness of Asia caused by *Neorickettsia sennetsu*. This pathogen is transmitted by ingestion of an infected helminth found in fish.

Diagnosis

- Doxycycline treatment should be initiated as soon as the disease is clinically suspected, and not postponed while awaiting laboratory confirmation.

- PCR of whole blood is commercially available, is highly specific, and is highly sensitive when performed during the early acute phase of illness; sensitivity decreases sharply after 48 hours of appropriate treatment.

- Immunofluorescence assay serology for immunogloblulin G antibodies to demonstrate a fourfold increase in titers between acute and convalescent samples is the gold standard for serodiagnosis.

- Visualization of morulae in white blood cells in a peripheral blood smear during the first week of illness is possible in some patients; however, this requires an astute microscopist to differentiate various structures and artifacts from morulae.

Treatment

- Doxycycline is the treatment of choice for adults and children *of all ages* and is most effective if started within the first 5 days of symptoms; alternative antibiotics may not be as effective at preventing severe complications or death.

- Recommended doxycycline dosage

- Children <45 kg: 2.2 mg/kg administered orally or intravenously every 12 hours

- Adults: 100 mg administered orally or intravenously every 12 hours

- Treatment is continued for at least 3 days after fever subsides and clinical improvement is documented (7–14 days total).

Francisella tularensis (Tularemia)

Lorry G. Rubin

Description of Pathogen and Epidemiology

Francisella tularensis, the etiologic agent of tularemia, is a small, fastidious, non–spore-forming, strictly aerobic gram-negative coccobacillus, which is nonmotile and nonpiliated and has a thin capsule composed mostly of lipid.[1] Tularemia is a zoonotic disease; in addition to humans, who are accidental hosts, more than 100 animal species are affected, particularly ground squirrels, rabbits, hares, voles, and muskrat.[2] Organisms most frequently are transmitted by ticks and biting flies,[3,4] but infections can be transmitted by direct contact with rabbits (other than domesticated rabbits) or other infected animals or their aerosols, especially related to skinning, dressing, or eating infected animals.[5] Domestic animals, especially cats but also sheep, hamsters,[6] and prairie dogs,[7] occasionally have been implicated.[1,8] Infections also can be transmitted through contaminated food or water[9] (possibly facilitated by the organism's survival within amebas) and by other biting vectors such as mosquitoes, fleas, and mites.[2–4] Fomites have been involved rarely, but person-to-person spread through contact with infected ulcers is not an important mode of transmission. There is a potential use of *F. tularensis* as a biologic weapon by intentional aerosol release of organisms, and *F. tularensis* is classified as a Category A agent of biologic threat by the Centers for Disease Control and Prevention (CDC).[10]

Although there are three subspecies, human disease is due primarily to two subspecies: *F. tularensis* subsp. *tularensis* (type A) and *F. tularensis* subsp. *holarctica* (formerly *palaearctica;* type B), both found only in the Northern Hemisphere.[1,11] Type A strains are more virulent than type B strains and are almost exclusively found in North America, with subclades A1a and A1b predominating in the eastern half of the United States, California, and Oregon and subclade A2 in the western US, whereas type B strains are found throughout the northern hemisphere but primarily in Europe and Asia. Cottontail rabbits, three ticks, *Amblyomma americanum* (Lone Star tick), *Dermacentor andersoni* (wood tick), and *Dermacentor variabilis* (dog tick), and biting flies are the main source of the type A subspecies.[1] In the US, most cases occur from June through September, the season correlating with increased tick activity. Approximately 100 to 200 cases of tularemia are reported annually. In 2012, 149 cases of tularemia were reported to the CDC from 26 states; the highest numbers of cases were in the contiguous states of Kansas, Missouri, Arkansas, and Oklahoma.[12] Approximately one fourth of cases occurred in children, and among all ages, children 1 through 4 years of age had the highest attack rate.[12]

Subspecies B is less virulent and often results in self-limited or subclinical infection, but it can cause typhoidal infection in immunocompromised patients[13] and pneumonia.[14] Subspecies B undergoes a waterborne cycle predominantly, with aquatic rodents such as muskrats, beavers, and ground voles as reservoirs. Transmission occurs through these rodents and mosquitoes. Subspecies B has a worldwide distribution in the northern hemisphere between latitudes 30°N and 71°N, which includes the continents of Europe, Asia, and North America.[11]

Pathogenesis and Immunity

The portal of entry most commonly is the skin through a tick or fly bite, crushing of a tick found on an animal, or a wound,[3,15] but entry also can occur through the conjunctivae, respiratory tract through aerosols, or oropharynx or rarely other parts of the gastrointestinal tract. *F. tularensis* is highly contagious; an inoculum size as small as 10 organisms through the skin is sufficient to induce tularemia in experimental infection of humans.[16] Regardless of the route of inoculation, bacteria usually invade regional lymph nodes and are disseminated to other organs and lymph nodes through bacteremia. *F. tularensis* is a facultative intracellular pathogen that survives and multiplies within macrophages. Infection generally results in humoral and cellular immune responses and protection against reinfection.[1] Protection chiefly is mediated by a cellular immune process in which bacteria are killed by macrophages activated by specifically committed T lymphocytes, but humoral immunity also has been demonstrated to contribute to immunity.[17] Protective immunity develops approximately 2 weeks after infection and is long lasting.

Clinical Manifestations

Important clues to the diagnosis of tularemia are a history of a tick or fly bite, exposure to live or dead rabbits or squirrels (or other wild or domestic animals, including other rodents), or consumption of poorly cooked game meat. Clinical manifestations appear after an incubation period of 2 to 10 days (ranging up to 21 days). The most common clinical syndromes include lymphadenopathy and are termed *ulceroglandular* and *glandular tularemia*, which account for 80% of reported cases. Other manifestations include oropharyngeal (the second most common finding in children in some series,[18]) oculoglandular, typhoidal, gastrointestinal, and pleuropulmonary syndromes (Table 171.1). Regional lymphadenopathy was present in 76% of 250 patients from Arkansas with tularemia.[4] Children with tularemia have constitutional symptoms (e.g., fever, chills, malaise, and fatigue) and gastrointestinal symptoms more frequently than do adults.[8]

TABLE 171.1

Clinical Forms of Tularemia

Clinical Form	Features
Glandular	Most common form; painful lymphadenitis with or without a papule that becomes an ulcer distal to the lymphadenitis; several lymph nodes or groups of lymph nodes can be involved; late suppuration common

Oculoglandular	Nodular conjunctivitis; painful preauricular lymphadenopathy
Oropharyngeal	Can simulate diphtheria; fever common; may have oral ulcers; associated with ingestion of contaminated meat or water
Typhoidal tularemia	Caused by ingestion of contaminated food; can have gastrointestinal tract ulceration; “sepsis” manifestation; high, prolonged fever usual
Gastrointestinal	Caused by ingestion of contaminated food; diarrhea and abdominal or back pain
Pneumonia	Rare in children; caused by aerosol exposure or hematogenous dissemination to lung; can be rapidly fatal

Ulceroglandular and Glandular Disease.

Ulceroglandular disease is manifest as swollen tender lymph nodes in the inguinal, cervical, or axillary regions, usually from the bite of a bloodsucking arthropod. Lymphadenopathy can be accompanied by systemic symptoms and typically is preceded by a painful, swollen papule or at times a vesicle distal to the involved lymph nodes that can evolve into an ulcer with raised edges. In young children, disease commonly manifests as lymphadenopathy without an ulcer.[19] Ulcers on the upper extremities usually result from exposure to infected mammals and occur in hunters and ranchers. Ulcerated lesions can persist for weeks if untreated. Lymphadenopathy in the inguinal region develops more frequently in patients with tick-associated infection than in those with rabbit-associated infection.[4] Frequently, multiple enlarged lymph nodes can be observed. In one pediatric series, most children had enlarged nodes in more than one cervical location or in a cervical chain and another regional location.[8,18] With mosquito-borne infection by type B strains in northern Finland, children had high fever and lymphadenopathy for 2 to 4 days, followed by low-grade fever and, commonly, a draining skin ulcer at the site of the mosquito bite.[11] Symptoms lasted a median of 26 days.

Oculoglandular Infection.

Oculoglandular disease results from conjunctival infection, usually acquired from contaminated fingers. Multiple, small, well-demarcated nodules and ulcers can be seen on the conjunctiva in association with inflammation and edema. Pain is a major symptom, causing the patient to seek medical care early in the course of infection, and sometimes before the development of preauricular lymphadenopathy. The associated enlarged preauricular lymph node is painful, a feature unique to oculoglandular infection due to *F. tularensis* and *Coccidioides,* which distinguishes it from the oculoglandular syndrome of cat-scratch disease, sporotrichosis, tuberculosis, and syphilis.[20]

Oropharyngeal Infection.

In the oropharyngeal form of tularemia, organisms enter the oropharyngeal mucosa from ingestion of inadequately cooked infected meat or contaminated milk or water. The clinical presentation is tonsillitis with throat pain out of proportion to the visible lesions and cervical lymphadenitis. Oral ulceration can develop, and there can be an oropharyngeal pseudomembrane similar to infection with *Corynebacterium diphtheriae.* Fever and other systemic symptoms can occur, and affected lymph nodes can suppurate. In the US, this form occurs most commonly in children.

Typhoidal Tularemia.

The signs and symptoms of typhoidal tularemia are similar to those of acute septicemia of any etiology and include high fever, chills, malaise, headache, vomiting, myalgia, and on occasion, photophobia. Hepatosplenomegaly is frequent, and diarrhea occurs occasionally. When typhoidal tularemia results from the ingestion of contaminated food, necrotic lesions can occur in the bowel.[4] Patients generally do not have cutaneous ulcers or lymphadenopathy. Untreated cases can have a fatal outcome or resolve after persistent fever for 2 to 3 weeks or longer. Patients also can have persistent diarrhea and abdominal or low-back pain from gastrointestinal tract tularemia without septicemic symptoms.

Pneumonia.

The pneumonic form of tularemia occurs almost exclusively in adults but has been reported in children exposed to an aerosol from an infected rabbit carcass run over by a lawn mower.[21] Intentional aerosol release as a biologic weapon would most commonly cause pneumonia (or typhoidal tularemia).[10] Pneumonia is the most common manifestation of tularemia acquired by laboratory workers. The usual radiographic finding is a unilateral lower lobe infiltrate, sometimes with associated pleural effusion or hilar adenopathy, or both. This form of infection can be severe or fatal. Pneumonia also can result from hematogenous dissemination to the lungs from typhoidal (30%–80% of cases) or ulceroglandular (10% –15% of cases) infections. *F. tularensis* infection causing fever and a pulmonary nodule has been reported in a stem cell transplant recipient.

Occasional Sites.

Rare manifestations of infection have included subcutaneous nodules resembling sporotrichosis, meningitis with a mononuclear cell predominance and hypoglycorrhachia,[22] encephalitis, pericarditis, endocarditis, peritonitis, and osteomyelitis. A variety of rashes can be seen, including maculopapular, pustular, and erythema nodosum.

Laboratory Findings and Diagnosis

Gram-stain smears prepared from exudate or tissue sections rarely can show weakly staining gram-negative coccobacilli in an extracellular or intracellular location. Organisms can be identified using an indirect immunofluorescent antibody test. The histopathology of affected lymph nodes shows follicular hyperplasia with mixed cellular inflammatory infiltrates, stellate and caseous necrosis with central suppuration, and epithelioid cell granulomas, findings similar to those seen in tuberculosis or *Bartonella henselae* infection.[23] A polymerase chain reaction assay to detect bacterial DNA in clinical specimens such as swabs of ulcers shows good sensitivity and excellent specificity.[24–26]

Culture of *F. tularensis* is not performed routinely in clinical laboratories because of the potential for aerosol inhalation and infection of laboratory personnel. Specimens should be collected cautiously and laboratory personnel notified when specimens suspected of harboring *F. tularensis* are submitted. Biosafety level 2 is recommended for clinical laboratory work and transfer of cultures to biosafety level 3 as soon as *F. tularensis* is suspected.[27] An enriched medium such as cysteine heart blood agar supplemented with 9% chocolatized sheep blood, chocolate agar enriched with cysteine, or buffered charcoal yeast extract agar (used for culture of *Legionella*) incubated aerobically is required for isolation of *F. tularensis* from clinical specimens.[1] Colonies are 1 to 2 mm in diameter, blue-grey, round, smooth, and slightly mucoid. Direct isolation can be achieved from ulcer scrapings, lymph node biopsy specimens, gastric washings, sputum, and occasionally, culture of blood using a radiometric or nonradiometric technique.[1,28] Identification of colonies can be made using biochemical tests complemented by immunologic and molecular methods.[1] Inoculation of laboratory animals such as mice or rabbits is a sensitive means of isolation of *F. tularensis* but is not used commonly for diagnosis.

The laboratory diagnosis of tularemia most often is confirmed by serologic testing using a tube agglutination or microagglutination assay. Antibodies generally are detectable at the end of the second or during the third week of illness. A fourfold increase or decrease in titer using a serum agglutination test is diagnostic; a single titer of >1 : 160 by tube agglutination or >1 : 128 by microagglutination is a presumptive positive result but also could reflect past infection.[1] Infected patients can have convalescent titers >1 : 1000, and a prozone phenomenon can be observed. Nonspecific cross-reactions can occur in patients infected with bacteria from the genus *Brucella* and certain other gram-negative bacteria.[1,27] The microagglutination assay is more sensitive than the tube agglutination test. An enzyme immunoassay using lipopolysaccharide antigens with immunoblot confirmation as a two-step procedure is more sensitive and specific than agglutination assays.[2,29] An immunochromatographic test has similar sensitivity and specificity to the microagglutination assay.[30] Assay for immunoglobulin M (IgM) antibodies is not useful because IgM antibodies are not present earlier than IgG antibodies and can persist for years.[1]

Treatment

Empiric antimicrobial therapy often must be initiated before serologic confirmation of infection is possible. A 7-day course of streptomycin or gentamicin,[31] or possibly amikacin, is the treatment of choice for tularemia, and defervescence is expected within a few days. Treatment is associated with a low relapse rate.[4] A 10-day or longer course may be administered in cases of severe disease and slow response. Streptomycin is given intramuscularly twice daily at a dose of 30 to 40 mg/kg per day with a maximum of 2 g/day. Gentamicin is given to children at a dose of 5-7.5 mg/kg/day as 2 or

3 doses, either intramuscularly or intravenously[10]; gentamicen has been administered once daily in adults.[32] A Jarisch-Herxheimer reaction can occur early during aminoglycoside treatment. Ciprofloxacin (or possibly levofloxacin) given for 10 to 14 days is the best alternative to aminoglycosides and may be used for treatment of mild infection and after relapse following aminoglycoside therapy.[33–37] Treatment with tetracycline or chloramphenicol often results in a prompt clinical response, but these agents are not bactericidal, and relapse occurs in at least one half of patients after cessation of therapy. In vitro susceptibility does not necessarily predict clinical efficacy. For example, *F. tularensis* is susceptible to third-generation cephalosporins in vitro, but all of 8 children treated with ceftriaxone failed to improve, indicating that this therapy is ineffective.[38] In a series of adult and pediatric patients from Missouri, 52% of 121 patients were hospitalized.[37] Suppurative lymph nodes that require surgical drainage occur in 14% to 33% of cases.[19] In one pediatric series, late suppuration after antibiotic therapy developed in 33% of children. In these cases, the aspirated or excised material was sterile.[8] The mortality rate for tularemia is <1%.[37]

In Finnish patients infected with *F. tularensis* subsp. *holarctica* (type B) organisms, the impact of antibiotics on the clinical course was uncertain, given the relatively mild course of infection.[11] By in vitro susceptibility testing, strains are susceptible to tetracyclines, aminoglycosides, fluoroquinolones, chloramphenicol, and rifampin. Strains generally are resistant to β-lactam antibiotics, carbapenems, aztreonam, and macrolide antibiotics.[39,40]

Prevention

The key to preventing tularemia is interruption of transmission, which can be achieved by prevention or timely detection of tick bites, avoidance of handling sick or dead rabbits or rodents, use of rubber gloves to handle game meat, and thorough cooking of meat. An investigational live, attenuated vaccine given pre-exposure using a multiple puncture technique was used in the US for research personnel with exposure to *F. tularensis* but is no longer available. This vaccine prevents respiratory tract infection in laboratory personnel but does not prevent ulceroglandular infection.[41,42] A new generation of live, attenuated vaccines is under development.[41] A 14-day course of doxycycline or ciprofloxacin has been recommended for prophylaxis of exposed persons following an intentional aerosol release of organisms or exposure in a laboratory.[10]

Key Points

Diagnosis and Management of Tularemia

Microbiology

- Small, aerobic gram-negative coccobacillus
- Nutritionally fastidious, requires enriched medium

Epidemiology

- Zoonotic infection
- Transmitted primarily by ticks, biting flies, or direct contact with rabbits or other infected animals or their aerosols
- Summer occurrence
- Potential for bioterrorism through intentional aerosol release of organisms

Clinical Features

- Incubation period: 2–10 days (up to 21 days)
- Most common presentation is lymphadenitis (“glandular”) with or without painful papule or ulcer at inoculation site; often lymphadenitis occurs at more than one site.
- Other presentations: oropharyngeal, oculoglandular, typhoidal, gastrointestinal, pleuropulmonary
- Fever is common.

Diagnosis

- Fourfold rise in serum immunoglobulin G antibody titer is confirmatory.
- Organism can be isolated from ulcers using enriched medium but is a biohazard for laboratory personnel.

Treatment

- Gentamicin or streptomycin for 7 days
- Alternative: ciprofloxacin for 10–14 days
- Ceftriaxone is ineffective; relapses occur after tetracycline.

Haemophilus influenzae

Joseph W. St. Geme III, Katherine A. Rempe

Haemophilus influenzae was first isolated by Pfieffer during the 1889 influenza pandemic.[1] For a time, *H. influenzae* was believed to be the causative agent of influenza and originally was called the *influenza bacillus.* However, subsequent studies demonstrated the fallacy of this notion, and the organism ultimately was given the genus name *Haemophilus,* meaning *blood loving.* The species name was chosen to reflect the historical association with influenza.

In 1995, the nucleotide sequence of the entire genome of *H. influenzae* strain Rd KW20 was published, representing the first organism to be sequenced completely. The annotated sequences of this strain and many others can be found at http://www.ncbi.nlm.nih.gov/genomeprj.

The Pathogen

H. influenzae is a nonmotile, non–spore-forming, gram-negative bacterium and typically appears as small coccobacilli, roughly 1 × 0.3 µm in size, although some isolates grow as long filaments. *H. influenzae* can grow aerobically or anaerobically. Aerobic growth requires two supplements known as factors X and V, whereas anaerobic growth requires only factor X. Factor X can be supplied by heat-stable iron-containing pigments, including hemin and hemoglobin, both of which represent a source of protoporphyrin IX. Factor V can be supplied by nicotinamide adenine dinucleotide, nicotinamide adenine dinucleotide phosphate, or nicotinamide nucleoside. Factor V is present in erythrocytes but must be released to sustain growth; as a consequence, standard blood agar is an unsatisfactory medium for propagating *H. influenzae*. Optimal growth is achieved on media enriched with erythrocytes that have been disrupted by heating (e.g., chocolate agar) or by peptic digestion (e.g., Fildes medium). Incubation in the presence of 5% to 10% carbon dioxide has a beneficial effect on the growth of some strains and is recommended for primary isolation.

Isolates of *H. influenzae* are classified according to their polysaccharide capsule.[2] As detailed in Table 172.1, six structurally and antigenically distinct capsular types (serotypes) exist and are designated as serotypes a through f. In addition, strains can be nonencapsulated; these strains are defined on the basis of their failure to react with typing antisera against capsular serotypes a through f and are referred to as *nontypable*. Worldwide, most clinical isolates are either type b or nontypable.[3,4]

TABLE 172.1

Chemical Composition of the Capsule of *Haemophilus influenzae*

Type	Sugar	*N*-Acetyl	Phosphate
a	Glucose, ribitol	–	+
b	Ribose, ribitol	–	+
c	Galactose, glucosamine	–	+
d	Glucosamine, mannosamine	–	+
e	Glucosamine, mannosamine	+	+
f	Galactosamine	+	+

Isolates also can be separated into subgroups called *biotypes* by using biochemical tests that determine the production of indole and the presence of ornithine decarboxylase and urease.[5] These reactions define eight biotypes designated I through VIII (Table 172.2). Data generated from biotyping studies indicate that type b isolates are predominantly biotype I.[6] Nontypable strains also can be biotype I, but in most collections they more often are biotype II or III.[7] Clinical isolates that are biotypes IV, V, VI, VII, or VIII are relatively uncommon and are almost always nontypable.

TABLE 172.2

***Haemophilus influenzae* Biotypes**

Biotype	Indole	Urease	Ornithine Decarboxylase
I	+	+	+
II	+	+	–
III	–	+	–
IV	–	+	+
V	+	–	+
VI	–	–	+
VII	+	–	–
VIII	–	–	–

Multilocus enzyme electrophoresis and a variety of other molecular techniques have been used to examine relatedness of isolates of *H. influenzae.* Studies using multilocus enzyme electrophoresis and other molecular techniques demonstrate that the population structure of encapsulated *H. influenzae* is clonal, with most isolates falling into a few common clonal groups.[8] Nontypable strains are genetically distinct and more heterogeneous than encapsulated *H. influenzae* and appear to lack clonality.[9]

Epidemiology

In the past, *H. influenzae* type b (Hib) strains were found in the upper respiratory tract of 3% to 5% of children and a small percentage of adults. In general, colonization rates with type b strains are even lower now because of routine immunization of infants with conjugate Hib vaccines, although exceptions exist.[10] Non–type b encapsulated *H. influenzae* stains are present in the nasopharynx of <2% of individuals, whereas nontypable strains colonize the respiratory tract of 40% to 80% of children and adults.[11–13]

Until approximately 1990, Hib was the leading cause of bacterial meningitis in children younger than 5 years in the United States, accounting for 8000 to 10,000 cases per year.[14] Hib also was the predominant cause of epiglottitis and a major cause of pyogenic arthritis, pneumonia, pericarditis, and facial cellulitis in young children. Approximately 1 in 200 children in the US experienced invasive (bacteremic) disease with this organism before the age of 5 years, with a peak incidence at 6 to 7 months of age. Invasive disease was more frequent in boys, African Americans, Alaskan

Eskimos, Apache and Navajo Indians, childcare center attendees, and children living in overcrowded conditions.[15–19] Medical conditions predisposing to invasive Hib disease included sickle cell disease, asplenia, human immunodeficiency virus (HIV) infection, certain immunodeficiency syndromes, and malignancies. Since 1990, the incidence of invasive Hib disease in the US has fallen by >99%, with only 30 cases reported in children younger than 5 years in 2013.[20–24] However, occasional shortages of vaccine have resulted in small clusters of cases in underimmunized young children.[25] In addition, there has been a modest resurgence of cases in recent years in parts of the US and in other developed countries.[26,27] Some children fail to respond to Hib vaccination and develop invasive Hib diseases, in most cases reflecting underlying immunodeficiency.[27,28]

Despite the overall successful reduction in invasive Hib disease in the US and other industrialized countries, Hib remains a common pathogen in many developing countries, where routine vaccines still are not available to most of the population. In these countries, Hib remains the leading cause of bacterial meningitis and the second leading cause of bacterial pneumonia.[29,30] Based on data from the World Health Organization, in 2012 vaccines against Hib were unavailable in 10 countries, most notably populous nations in Asia and parts of Africa (http://www.who.int/immunization/topics/hib/en/). As of 2013 only 52% of infants worldwide had received three doses of Hib vaccine by age 1 year (http://www.who.int/immunization/topics/hib/en/).

Nontypable strains of *H. influenzae* are a common cause of localized respiratory tract infections in children and adults.[31,32] In children, these organisms are the most common cause of purulent conjunctivitis, the most common or second most common cause of acute otitis media, and a frequent cause of sinusitis. In children in developing countries, nontypable *H. influenzae* is a frequent cause of pneumonia and an important source of mortality. In adults, nontypable *H. influenzae* is an especially common cause of community-associated pneumonia and exacerbations of underlying lower airway and lung disease and also accounts for a substantial proportion of cases of otitis media and sinusitis. Beyond producing localized disease, nontypable *H. influenzae* is an occasional cause of serious systemic disease such as septicemia, meningitis, and pyogenic arthritis, especially in neonates, pregnant women, and individuals with compromised immune function.[33,34]

Disease due to *H. influenzae* non−type b encapsulated strains occurs occasionally, in both developed and underdeveloped countries. For example, a 2010 study in Canada found that approximately 20% of invasive *H. influenzae* infections were caused by encapsulated non−type b strains.[35] Based on recent reports in the US, Canada, and Europe, cases of *H. influenzae* type a, type e, and type f invasive disease are increasing in frequency and are fatal in up to 20% of children and 30% of adults.[36–42]

Pathogenesis

Generally, *H. influenzae* is transmitted by airborne droplets or by direct contact with respiratory tract secretions. Colonization with a particular strain can persist for weeks to months, and most individuals remain asymptomatic throughout this period.[43] A variety of bacterial factors appear to influence the process of respiratory tract colonization. For example, the lipid A component of *H. influenzae* lipopolysaccharide (LPS), peptidoglycan fragments, protein kinase C_ε, and a surface-associated glycerophosphodiester phosphodiesterase called *protein D* or *GlpQ* (which allows choline to be transferred from the host to the bacterial surface) cause ciliostasis and thereby interfere with mucociliary clearance.[44–48] In addition, both pilus and nonpilus adherence factors exist and are known to mediate binding to mucus and to respiratory epithelium.[49–53] Like other mucosal pathogens, *H. influenzae* produces immunoglobulin A_1 (IgA_1) protease, an enzyme that cleaves human IgA_1 and presumably facilitates evasion of the local immune response.[54,55] Bacterial antigenic variation, entry into host cells, penetration between host cells (paracytosis), changes in LPS, and biofilm formation also may promote evasion of local immunity and persistence on mucosal surfaces.[56–66]

In certain circumstances, colonization is followed by contiguous spread within the respiratory tract, resulting in local disease in the middle ear, sinuses, conjunctiva, or lungs (Fig. 172.1). Anatomic factors, deficiencies in local immune function, concurrent viral respiratory infection, exposure to cigarette smoke, and allergies predispose to localized respiratory tract disease.[67] On occasion, bacteria penetrate the nasopharyngeal epithelial barrier and enter the bloodstream (see Fig. 172.1). The determinants of this event remain poorly defined but may include bacterial LPS.[68] Of note, penetration of the epithelial barrier appears to involve the separation of tight junctions, which allows bacteria to migrate between cells and into the subepithelial space.[69] In most cases, bacteremia probably is transient. However, in nonimmune hosts, intravascular bacteria that express the type b capsule sometimes are able to survive, replicate, and disseminate to distant sites. In the absence of specific antibody, the type b polysaccharide capsule promotes resistance to serum bactericidal activity and to phagocytosis. A variety of other factors also have been implicated in resistance to serum killing, including binding of factor H and vitronectin by bacterial surface proteins.[65,70–73]

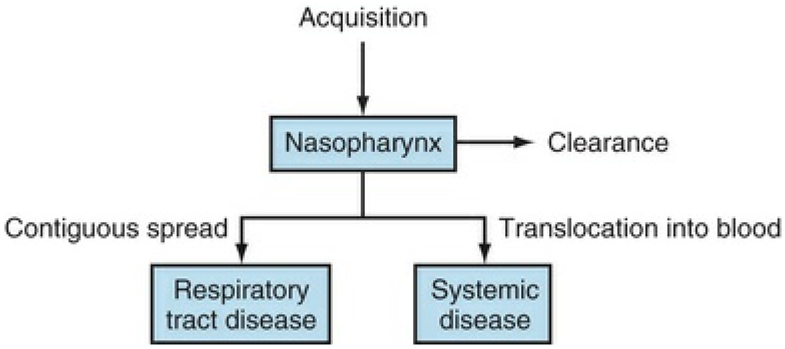

FIGURE 172.1 Pathogenic sequence for disease caused by *Haemophilus influenzae.*

Immunity

The age-associated susceptibility to Hib disease is inversely related to the presence of serum bactericidal antibody, much of which is directed against the type b polysaccharide capsule.[74,75] Antibody against the type b capsule activates complement-mediated bacterial killing and facilitates phagocytosis by opsonization.[76] Based on studies performed in the pre-Hib vaccine era, during the first 3 to 6 months of life, most infants have protective levels of maternally acquired anticapsular antibody. These levels gradually decline, reach a nadir by 6 to 12 months of age, and remain low for the next few years. By the age of 5 years, virtually all individuals have acquired anticapsular antibody, in some cases as a result of colonization with Hib or probably more frequently from exposure to commensals (e.g., *Escherichia coli* K100) or ingested food possessing cross-reactive epitopes.[77–79] Antibodies to noncapsular antigens such as LPS and outer membrane proteins also contribute to serum bactericidal and opsonic activity.[80,81]

At the time of infection, serum antibodies against the serotype b capsule are low or absent. In children younger than 2 years, levels remain low during convalescence because of an age-related deficiency in the ability to respond to polysaccharide antigens (T-lymphocyte–independent antigens).[82] In older children, infection stimulates a brisk increase in the level of anticapsular antibody. Natural infection also is associated with the formation of antibodies to LPS and surface-associated proteins, and these antibodies contribute to protection against recurrent Hib disease.

The complement system is critical in host defense against Hib disease, and patients with congenital deficiencies of certain complement components, including C2, C3, and C4, have increased susceptibility to Hib disease.[83] Hib is capable of activating both the classic and the alternate complement pathways.[83,84] Early in the course of infection in nonimmune hosts, the alternate pathway probably is more important, whereas at later stages, the antibody-dependent classic pathway is more likely to predominate. Clearance of bacteremia with type b organisms also requires an intact mononuclear phagocytic system, thus explaining the higher incidence of Hib bloodstream infection in patients with splenic dysfunction.

Immunity to nontypable organisms involves both systemic and local antibody responses. Moreover, evidence suggests that systemic priming functions to enhance the local response. Based on studies of patients with otitis media and bronchitis, it appears that the immune response to nontypable *H. influenzae* often is strain specific. For example, Faden and colleagues observed a population of children prospectively for 2 years and identified 8 subjects who experienced two separate episodes of acute otitis media from nontypable *H. influenzae*.[85] In all 8 patients, the second episode was caused by a different strain. Serum was collected from 6 of these patients at the time of the second episode and was found uniformly to contain bactericidal antibody against the first strain. However, only 3 of these 6 samples possessed measurable bactericidal antibody against the second strain, thus indicating the absence of cross-reacting bactericidal activity. Consistent with these findings, Musher and associates found that adsorption of normal human serum with nontypable *H. influenzae* removed bactericidal activity against the adsorbing isolate but not necessarily against other nontypable strains.[86] Major targets of the antibody response to infection include the P2 major outer membrane protein, the HMW1/HMW2 and Hia adhesins, protein D, and LPS.[87]

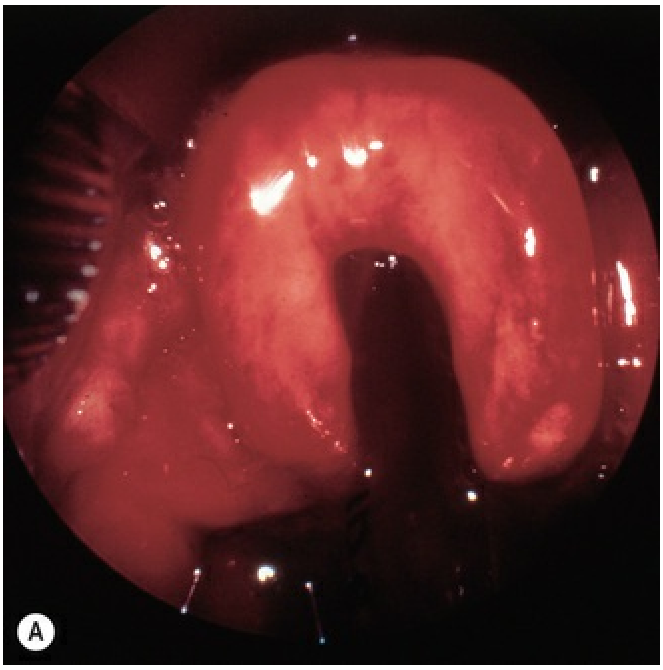
Clinical Manifestations of *Haemophilus influenzae* Type b Infection

Meningitis

Meningitis is the most common and most serious form of Hib disease. Symptoms typically include fever, irritability, lethargy, and vomiting. Antecedent symptoms of an upper respiratory tract infection are common. Occasionally, the course is fulminant, with rapid neurologic deterioration leading to respiratory arrest.[88] Shock is present in 20% of cases of meningitis and can be associated with coagulopathy and purpura.[89] An association of Hib meningitis and anemia is clear and appears to be related, at least partly, to adsorption of capsular antigen to the red cell surface with secondary immune-mediated hemolysis.[90] Complications of Hib meningitis include subdural effusion or empyema, ischemic or hemorrhagic cortical infarction, cerebritis, ventriculitis, intracerebral abscess, and hydrocephalus. The overall mortality rate is approximately 5%. Among survivors, between 5% and 10% have permanent sensorineural hearing loss, and about 30% have some other significant handicap. If subtle neurologic deficits are sought, up to one half of survivors have sequelae.[91–93]

Epiglottitis

Epiglottitis is a life-threatening infection involving cellulitis of the epiglottis and the aryepiglottic folds. Complete obliteration of the vallecular and piriform sinuses is typical, and acute airway obstruction can occur. Most affected children are between 2 and 7 years of age. Symptoms often are sudden in onset and classically include high fever, sore throat, stridor, and dyspnea progressing rapidly to dysphagia, pooling of oral secretions, and drooling. In children younger than 2 years, fever can be low grade, a croup-like cough can be present, and dysphagia and drooling sometimes are absent. Regardless of age, the patient usually is restless and anxious and adopts a sitting position with the neck extended and the chin protruding to reduce airway obstruction. Abrupt deterioration can occur within a few hours and result in death unless an artificial airway is established. Direct laryngoscopy at the time of controlled placement of an endotracheal tube reveals a red and swollen epiglottis and swollen aryepiglottic folds (Fig. 172.2A, B). On a lateral neck radiograph, the swollen epiglottis produces the *thumb sign* (Fig. 172.2C).



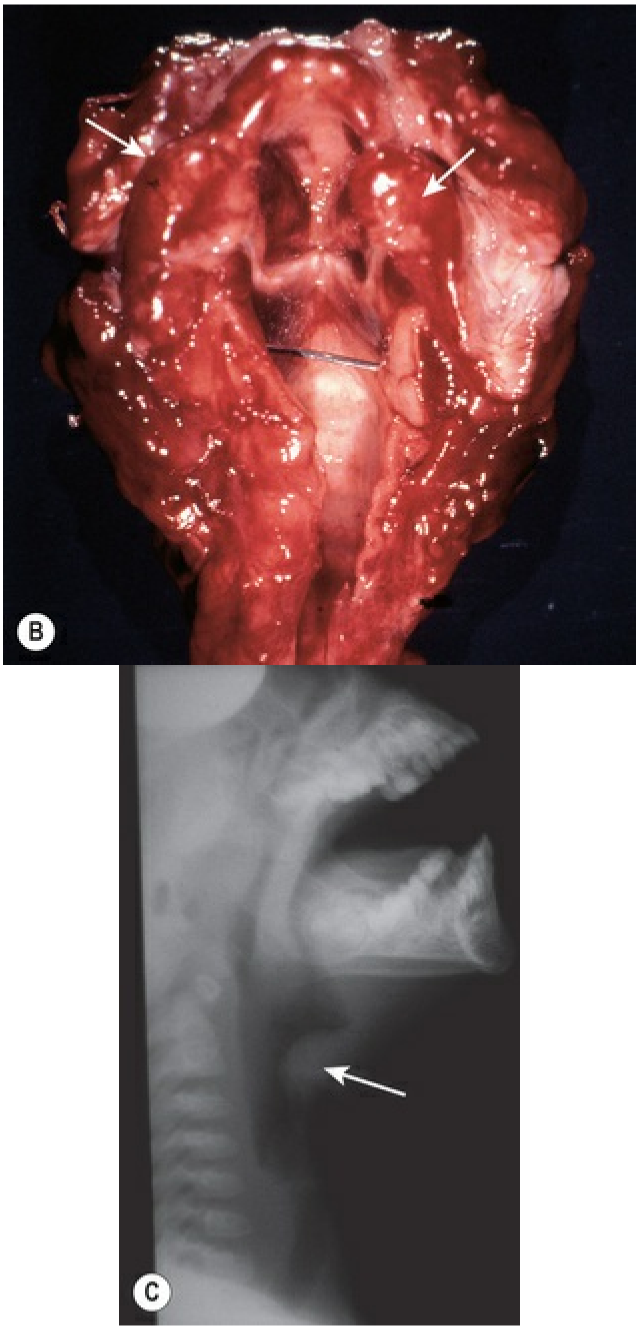


FIGURE 172.2 Clinical findings in confirmed cases of *Haemophilus influenzae* type b epiglottitis. Direct laryngoscopic findings of erythema and edema of the epiglottis in a 4-year-old child (A). Gross specimen from a fatal case shows erythema and edema predominantly of arytenoids structures *(arrows)* and aryepiglottic folds (B). Lateral neck examination. Lateral neck radiograph in another case shows thumbprint appearance *(arrow)* of the swollen epiglottis (C). (Courtesy of S. S. Long.)

Pneumonia

Patients with Hib pneumonia typically have a consolidative pulmonary infiltrate. In 50% of cases, evidence of pleural involvement can be seen on the initial chest radiograph, and up to 90% of these patients have pleural fluid recoverable by thoracentesis. Generally, Hib pneumonia is more insidious in onset than is pneumonia from *Staphylococcus aureus* or *Streptococcus pneumoniae.* Nearly one fourth of patients have concomitant meningitis or epiglottitis. An important complication is contiguous spread to the pericardium and subsequent purulent pericarditis, which is manifest as severe dyspnea (grunting in infants), tachycardia, and cardiac failure. Although patients with Hib pneumonia often have a persistent pleural reaction with secondary restrictive lung function at the time of hospital discharge, long-term abnormalities are rare.

Osteoarticular Infection

Historically, Hib was the most common cause of pyogenic arthritis in children younger than 2 years, usually of a single large weight-bearing joint (hip, knee, or ankle).[94] In 10% to 20% of cases, contiguous osteomyelitis is present. Osteomyelitis alone is unusual. The response to systemic antibiotics combined with prompt drainage of the joint is dramatic, but long-term follow up is important because residual joint dysfunction can occur. On occasion, culture-negative arthritis develops during treatment of *H. influenzae* meningitis, presumably as a result of immune complex deposition in the joint.[95] In 75% of patients with reactive arthritis, signs of joint inflammation begin 1 week or more after therapy is begun.

Bacteremic Cellulitis

Cellulitis is the result of a metastatic focus of bacteremia and is seen predominantly in young children. Typically, the patient is febrile and has a warm, tender area of erythema or violaceous discoloration on the cheek or in the periorbital area. Facial (buccal) cellulitis almost invariably occurs in children younger than 1 year. The age of the child, the location of the cellulitis, and the occasional distinctive violaceous color should suggest the etiology (Fig. 172.3). Aspirate cultures, either from the center of the lesion or the leading edge, usually yield the organism. Concomitant bacteremia is present in most patients, and another focus of infection such as meningitis develops in approximately 10% of cases.[96,97] Cellulitis that occurs as a complication of trauma to the skin is not caused by *H. influenzae.*

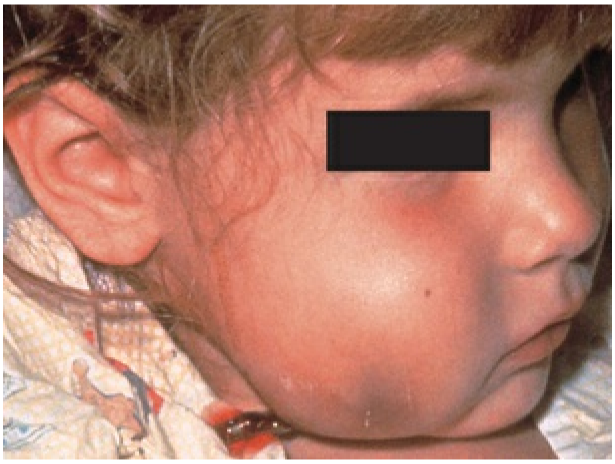

FIGURE 172.3 Buccal cellulitis in a 14-month-old girl whose blood culture yielded *Haemophilus influenzae* type b. Note distinctive site of cellulitis on the lower cheek and violaceous color. (Courtesy of S. S. Long.)

Other Infections

Other manifestations of Hib disease include occult bacteremia (which rarely is self-limited), otitis media, orbital cellulitis, septicemia, endophthalmitis, urinary tract infection, and peritonitis. In addition, purulent pericarditis can result from direct seeding from bacteremia.

Infection Due to Nontypable *Haemophilus influenzae*

Respiratory Tract Infection

Contemporary studies examining the bacteriology of acute otitis media consistently demonstrate *H. influenzae* as the most common pathogen.[98–101] Among *H. influenzae* isolates, almost all are nontypable. According to studies reported from the US and Scandinavia, the peak age-specific incidence of *H. influenzae* acute otitis media occurs between 6 and 15 months of age.[102,103] Characteristic manifestations include ear pain, fever, irritability, sleep disturbance, and otorrhea. On examination, the tympanic membrane usually is red or yellow and bulging, with distorted landmarks, and pneumatic otoscopy reveals decreased mobility. Additionally, nontypable *H. influenzae* is the pathogen implicated most commonly in otitis media with effusion and accounts for >40% of cases with positive tympanocentesis cultures.[104,105] Nontypable *H. influenzae* also has been associated with dual infection of the conjunctiva and the middle ear.[106] These infections occur primarily during the winter months and have been termed the *conjunctivitis-otitis syndrome*. Nontypable strains also are an important cause of isolated conjunctivitis (see Chapter 173).

Among children with acute sinusitis, *S. pneumoniae, H. influenzae,* and *Moraxella catarrhalis* account for nearly three fourths of recoverable isolates, with most *H. influenzae* strains being nontypable.[107,108] Most patients with sinusitis have persistent nasal discharge or cough that lasts longer than 10 days without improvement. Others present acutely with high fever and purulent nasal discharge. Physical examination often reveals tenderness over the involved paranasal sinuses. Data on the microbiology of chronic sinusitis are limited but suggest that nontypable *H. influenzae* is a prominent pathogen.[109] Several studies have examined the predictive value of surface cultures of the nose, throat, or nasopharynx in patients with acute or chronic sinusitis. Although the organisms isolated from direct aspiration of infected sinuses generally are recovered from surface cultures, they are not consistently the predominant organisms. Surface cultures are of minimal value in establishing an etiologic agent.

Because sputum frequently is contaminated by pharyngeal bacterial flora, interpretation of the growth of *H. influenzae* from sputum culture is difficult. However, there is substantial evidence that nontypable *H. influenzae* causes bacterial pneumonia, especially in children in developing countries, elderly people, and patients with frequent aspiration or underlying lung disease. Among children in developing countries with clinical evidence of pneumonia, lung aspiration studies demonstrate that bacteria can be recovered >60% of the time; up to half of these isolates are nontypable *H. influenzae.*[110,111]

Meningitis

Nontypable *H. influenzae* is an occasional cause of meningitis and, unlike Hib, usually occurs by direct extension from a contiguous focus of infection. Most individuals with nontypable *H. influenzae* meningitis have a predisposing factor, such as sinusitis, otitis media, head trauma, or another anomaly resulting in cerebrospinal fluid leak. In patients with recurrent bacterial meningitis, nontypable *H. influenzae* is the second most common cause (after *S. pneumoniae*) and generally enters the central nervous system through a communication between a parameningeal site and the subarachnoid space.[112]

Neonatal Infection

Nontypable *H. influenzae* is a well-recognized neonatal pathogen.[113–117] (Non−type b encapsulated strains occasionally also have been implicated in this setting.) In most cases, *H. influenzae* produces an early-onset neonatal syndrome similar to that caused by group B streptococci. Disease occurs primarily in premature neonates and is associated with a mortality rate of nearly 50%. Symptoms develop in most infants within the first few hours of life, with pneumonia and respiratory distress dominating the clinical picture. Meningitis occurs infrequently. *H. influenzae* usually can be isolated from the genitourinary tract of mothers of infected infants, often in association with maternal postpartum endometritis. Paired maternal-infant isolates have been confirmed to be the same strain by a variety of methods.[118,119] A substantial percentage of these isolates are biotype IV, a subgroup of nontypable *H. influenzae* found uncommonly at other sites of infection.[115] Analysis of these biotype IV strains by multilocus enzyme electrophoresis indicates divergence from other *H. influenzae,* and chromosomal DNA hybridization studies and 16S rRNA gene sequencing suggest that these strains represent a distinct *Haemophilus* species most similar to

H. haemolyticus, leading to the designation *Haemophilus* cryptic genospecies.[120,121]

Other Infections

Nontypable *H. influenzae* has been reported rarely as a cause of endocarditis, pericarditis, pyogenic arthritis, osteomyelitis, epiglottitis, cellulitis, urinary tract infection, intra-abdominal infection, and occult bacteremia.[67]

Diagnosis

In most cases of invasive Hib disease, blood cultures are positive. When meningitis is present, bacteria almost always can be recovered from CSF. In patients with epiglottitis, culture of the epiglottis usually is positive, but specimens should be obtained only after establishment of an artificial airway. *H. influenzae* is often cultivated from samples of pleural fluid, joint fluid, or pericardial fluid in affected patients. In roughly 70% of patients with *H. influenzae* meningitis, Gram stain of centrifuged CSF is positive for gram-negative coccobacilli. The sensitivity of CSF Gram stain correlates with bacterial density and ranges from 0% in the presence of $<10^3$ colony-forming units per milliliter to nearly 100% when the density is $\geq 10^5$ colony-forming units per milliliter.[122]

Type b capsular polysaccharide is secreted during bacterial growth, and detection of capsular antigen can aid in diagnosis. Methods available for this purpose include latex particle agglutination, coagglutination, countercurrent immunoelectrophoresis, and enzyme immunoassay. Serum, CSF, urine, and other normally sterile body fluids are suitable for examination for capsular antigen. Antigen detection techniques are most valuable in patients who have previously received antibiotic therapy and have sterile cultures, or to facilitate early chemoprophylaxis of contacts. In cases of culture-proven meningitis, capsular antigen is detected roughly 90% of the time in CSF and even more frequently in concentrated urine. False-positive reactions occur occasionally as a result of cross-reactivity with *E. coli, S. pneumoniae,* staphylococci, or meningococci. Of note, Hib conjugate vaccines can produce positive reactions in urine and CSF for days to weeks after vaccination.[123–127]

Because *H. influenzae* is a common commensal organism in the upper respiratory tract, establishing *H. influenzae* as an etiology of localized respiratory tract disease is challenging. Procedures such as tympanocentesis, sinus aspiration, tracheal or lung aspiration, bronchoscopy, and bronchoalveolar lavage can provide a definitive diagnosis when required, as in patients with persistent or recurrent infection or underlying immunodeficiency.

Treatment

Resistance to ampicillin now is common among isolates of *H. influenzae,* with the incidence in the range of 40% in some communities.[128,129] Ampicillin should never be used alone as empiric therapy of invasive disease. Ampicillin resistance usually is related to plasmid-mediated production of β-lactamase but occasionally is due to decreased affinity of certain penicillin binding proteins (in particular PBP3).[130] To detect both forms of resistance, a β-lactamase assay should be performed along with disk or broth-dilution susceptibility tests. The third-generation cephalosporins are the therapy of choice for *H. influenzae* meningitis. Both cefotaxime and ceftriaxone have potent activity against *H. influenzae* (including isolates that produce β-lactamase and isolates with an altered penicillin-binding protein) and achieve high levels in CSF. For infections outside the central nervous system, cefuroxime and ampicillin-sulbactam are suitable alternatives.

For patients with meningitis, dexamethasone therapy in a dose of 0.15 mg/kg every 6 hours for the first 2 or 4 days of treatment appears to decrease the likelihood of neurologic sequelae, including hearing deficit.[131–133] Dexamethasone should be initiated before the first dose of antibiotic whenever possible. Patients with epiglottitis require placement of an artificial airway, and children with pneumonia often need treatment with supplemental oxygen. When pleural empyema, purulent pericarditis, or pyogenic arthritis is present, prompt drainage is essential for a good outcome.

Otitis media and sinusitis are treated effectively with oral agents to which the causative strain is susceptible. Table 172.3 shows comparative minimal inhibitory concentrations inhibitory to 90% of isolates (MIC_{90}) for selected oral antibiotics.

TABLE 172.3

In Vitro Activity of Selected Oral Agents Against *Haemophilus influenzae*

Antibiotic	MIC_{90} (μg/mL)
Cephalexin	8
Cefaclor	8
Cefprozil	8
Cefdinir	1
Cefuroxime	0.5
Cefpodoxime	0.06
Cefixime	0.06
Cefditoren	0.03
Amoxicillin-clavulanate	16
Trimethoprim-sulfamethoxazole	0.5
Clarithromycin	8
Azithromycin	1

MIC_{90}, minimal inhibitory concentration required to inhibit the growth of 90% of strains.

Prevention

Vaccination

First-generation vaccines against Hib were purified type b capsular material, polyribosylribitol phosphate (PRP). These vaccines were not effective in children younger than 24 months and had variable efficacy in children 24 months and older.[134,135] Second-generation vaccines contain PRP or a derivative of PRP conjugated to an immunogenic carrier protein, are effective in infants, and have replaced the earlier vaccines. Currently, three conjugate vaccines are licensed, all differing to some extent in the size of the polysaccharide, chemical linkage between the polysaccharide and the carrier, and the type of protein carrier (Table 172.4).[136] Among these three vaccines, PRP-T (PRP-tetanus toxoid) and PRP-OMP (PRP–*Neisseria meningitidis* outer membrane protein) are available in the US. As a result of differences in immunogenicity, the primary series in infancy consists of three doses (at 2, 4, and 6 months of age) for PRP-T and two doses (at 2 and 4 months) for PRP-OMP. Regardless of the particular vaccine used during the first year of life, a booster dose should be administered between 12 and 15 months of age. Combination vaccines that contain an Hib conjugate formulation licensed and available in the US are MenCY/PRP-T (MenHibRix) and DTaP-IPV/PRP-T (Pentacel).

TABLE 172.4

Haemophilus influenzae Type b Conjugate Vaccines

Vaccine	Trade Name	Polysaccharide	Linkage	Protein Carrier
PRP-OMP[a]	PedvaxHIB	Medium	Thioether	*Neisseria meningitidis* outer membrane protein
PRP-T[a]	ActHIB	Large	6-Carbon	Tetanus toxoid
PRP-T	Hiberix	Large	6-Carbon	Tetanus toxoid

[a] Additional combination vaccines have been licensed that include these conjugate vaccines. DTaP/PRP-T (TriHIBit) contains DTaP vaccine and PRP-T; DTaP-IPV/PRP-T (Pentacel) contains DTaP vaccine, inactivated poliovirus vaccine, and PRP-T.

OMP, outer membrane protein; PRP, polyribosylribitol phosphate; PRP-T, PRP-tetanus toxoid.

Children with sickle cell disease, anatomic or functional asplenia, HIV infection, or IgG2 subclass deficiency, patients receiving chemotherapy for malignancies, and patients who have undergone bone marrow transplantation have an increased risk of invasive Hib disease. Conjugate vaccine should be considered for those who are unvaccinated. Two doses (at least 1 month apart) are recommended for children 12 to 59 months of age and one dose for those 60 months or older. (For further consideration, see the *2015 Red Book* by the American Academy of Pediatrics Committee on Infectious Diseases and Section 1, Active and Passive Immunization.).[136]

All of the conjugate vaccines are well tolerated, with the most common adverse effect being short-lived redness and swelling at the site of injection. Postlicensing studies indicate that the existing conjugate vaccines are highly effective against Hib disease and reduce rates of nasopharyngeal colonization. These vaccines confer no protection against non–type b or nontypable strains.

A 10-valent pneumococcal nontypable *H. influenzae* protein D –conjugate vaccine was examined in a randomized, double-blind efficacy trial and was found to be associated with an efficacy against nontypable *H. influenzae* otitis media of 35·3% [95% confidence interval, 1.8%–57.4%].[87] This vaccine has been licensed in more than 40 countries but is not yet licensed in the US. A variety of other nontypable *H. influenzae* surface proteins also are under study as candidate vaccine antigens.[137]

Chemoprophylaxis

Chemoprophylaxis is an important intervention for preventing invasive Hib disease.[125] The intent is to eradicate nasopharyngeal colonization and thereby interrupt transmission. In households with one or more infants younger than 12 months who have not received the complete Hib primary vaccine series, all household contacts should receive rifampin prophylaxis. The same applies in households with children younger than 4 years who are incompletely vaccinated and in families with a fully vaccinated but immunocompromised child even if the child is older than 48 months. In addition, when two or more cases of invasive disease occur within a 60-day period in attendees of a group childcare facility and incompletely vaccinated children attend the facility, rifampin is recommended for all attendees and supervisory personnel. Management after a single case at a childcare facility is controversial and depends on the age and immunization status of the attendees and the duration of daily contact between attendees and the index patient. In-home group childcare settings are managed like families. For prophylaxis, rifampin is given once a day for 4 days (20 mg/kg; maximal dose, 600 mg; some would administer a dose of 10 mg/kg daily for infants younger than 1 month).

Treatment of the index case with cefotaxime or ceftriaxone eradicates Hib colonization, eliminating the need for prophylaxis in this individual. However, index patients who are treated with other agents (e.g., ampicillin or meropenem) and who are younger than 2 years or have a susceptible household contact should receive rifampin prophylaxis at the end of systemic treatment for invasive disease.

Chemoprophylaxis for recurrent otitis media from nontypable *H. influenzae* (or other typical pathogens) is not recommended due to increasing concerns over antibiotic resistance.[138]

Key Points

Diagnosis and Management of *Haemophilus influenzae* Infection

Microbiology

- Nonmotile, non–spore-forming, gram-negative coccobacillus
- Grows aerobically and anaerobically; requires factor X and factor V for aerobic growth and factor X for anaerobic growth
- Optimal growth is achieved on media enriched with erythrocytes that have been disrupted by heating (e.g., chocolate agar) or by peptic digestion (e.g., Fildes medium).
- Isolates are classified according to polysaccharide capsule (encapsulated forms are designated serotypes a–f; nonencapsulated forms are designated nontypable).

Epidemiology

- Normal nasopharyngeal flora; type b and non–type b encapsulated stains generally colonize nasopharynx of <3% of individuals, whereas nontypable strains colonize the nasopharynx of 40% to 80% of children and adults.
- Hib was leading cause of bacterial meningitis and other invasive diseases in children younger than 5 years in the United States until routine infant immunization in 1990; remains a common pathogen in young children in countries without routine immunization.
- Type a, type e, and type f invasive disease appears to be increasing in frequency in the US, Canada, and Europe.
- Nontypable strains are a common cause of localized respiratory tract disease in both children and adults.

Diagnosis

- Culture from a normally sterile site (blood, cerebrospinal fluid, joint fluid, pleural fluid, pericardial fluid, epiglottis)
- Culture of fluid obtained by tympanocentesis, sinus aspiration, tracheal or lung aspiration, bronchoscopy, and bronchoalveolar

lavage when specific microbiologic diagnosis is required

Treatment

- About 40% of isolates are ampicillin resistant, in most cases because of β-lactamase production.
- Ampicillin should never be used alone as empiric therapy of invasive disease but can be used as definitive therapy for ampicillin-susceptible isolates.
- A third-generation cephalosporin is the therapy of choice for meningitis.
- A variety of β-lactam and other oral agents are suitable for otitis media, sinusitis, and most other respiratory tract infections.

Other *Haemophilus* Species and *Aggregatibacter* Species

Emily Souder, Jennifer Vodzak

Of the *Haemophilus* species, *H. influenzae* causes by far the most human disease. Several other members of this genus, however, are capable of causing clinical illness. These include *H. influenzae* biogroup *aegyptius, H. ducreyi, H. parainfluenzae, H. pittmaniae, H. sputorum, H. haemolyticus, H. parahaemolyticus,* and the ill-defined species *H. paraphrohaemolyticus*.[1] Three former *Haemophilus* spp. known to cause human disease have been reclassified into the genus *Aggregatibacter,* as follows: *H. aphrophilus* and *H. paraphrophilus* are now the single species *A. aphrophilus*, and *H. segnis* now is *A. segnis*.[2,3] Reclassification is based on phenotypic properties and molecular analyses (16S rRNA analysis and DNA-DNA hybridization studies). The genus name *Aggregatibacter* refers to "rod-shaped bacteria that aggregate with others," and aptly describes their tendency to adhere to test tube walls (see also Chapter 181).

The genus *Haemophilus* is classified in the family Pasteurellaceae. Members of this genus are small, pleomorphic, facultatively anaerobic, gram-negative coccobacilli. *Haemophilus* spp. can be distinguished based on need for X factor (hemin) or V factor (nicotinamide) for in vitro growth, ability to lyse horse erythrocytes, and production of catalase (Table 173.1). With the exception of *H. ducreyi*, all *Haemophilus* spp. ferment glucose. *H. ducreyi* grows optimally at 33°C, whereas other species grow optimally at 35°C–37°C. In general, haemophili grow best in a humid environment enriched with 5%–10% carbon dioxide.[1] Both *A. aphrophilus* and *A. segnis* are small gram-negative bacilli that do not require X factor, have variable dependence on V factor, and ferment glucose.[2]

Haemophilus influenzae Biogroup Aegyptius

The Koch-Weeks bacillus, originally observed in Egyptian children with conjunctivitis by Koch in 1883 and further characterized by Weeks in 1886, was designated *Haemophilus aegyptius* in 1950.[4] Controversy over whether *H. aegyptius* merited classification as a separate species from *H. influenzae,* already extant at that time, persisted. Although there are phenotypic and pathogenetic differences between *H. aegyptius* and *H. influenza,*[4–8] no single characteristic distinguishes the two organisms unequivocally, and DNA hybridization studies indicate high relatedness.[9,10] The Koch-Weeks bacillus, therefore, presently is considered as a distinct subgroup of *H. influenzae* biotype III and termed *H. influenzae* biogroup *aegyptius*.[8]

In the United States, *H. influenzae* biogroup *aegyptius* has been a cause of seasonal acute conjunctivitis in southern states during warmer months. Studies performed in Texas[11] and Georgia[12] found this organism to be the leading cause of acute purulent conjunctivitis among children in the 1930s to 1950s. Some studies have suggested that the eye gnat (*Hippelates pusio*) might serve as a transmission vector (hence the lay term, "gnat sore eyes"), although this role has not been proved.

H. influenzae biogroup *aegyptius* also can cause severe infection, Brazilian purpuric fever (BPF). The first known cases of BPF occurred in 1984 in rural Brazil, when 10 children died from a rapidly progressive illness characterized by fever, abdominal pain, vomiting, purpura, and vascular collapse.[13] Epidemiologic investigations noted strong association with recent history of purulent conjunctivitis. When another outbreak occurred in Brazil in 1986, the etiology of BPF was established.[14] *H. influenzae* biogroup *aegyptius* was isolated from 9 blood cultures and 1 hemorrhagic cerebrospinal fluid culture from 10 clinically affected children.

The age range of reported cases of BPF is 3 months to 10 years, with peak incidence between 1 and 4 years. About 90% of patients have a recent history of conjunctivitis, and about 70% of identified cases have been fatal.[15,16] In Brazil, epidemic and sporadic cases have been reported from the states of São Paulo, Paraná, and Mato Grosso.[13–16] Single cases of BPF with bloodstream infection due to *H. influenzae* biogroup *aegyptius* have been reported from Australia[17] and the United States.[18] Molecular studies demonstrated isolates were unique clones.[18,19] Extensive analyses, including examination of protein profiles, ribotyping, plasmid restriction patterns, seroagglutination, and multilocus sequencing,[20] indicate that the isolates causing BPF in Brazil belong to a single clone that is distinct from other strains of *H. influenzae* biogroup *aegyptius* in Brazil and other countries.[10]

Interestingly, there were no reports of BPF from the mid-1990s until 2007 when 7 suspected cases of BPF occurred in children in

Anajas, Brazil, including 5 deaths within 24 hours.[21] Speculation about the apparent “disappearance” of this illness includes natural history of a bacterial species, underrecognition or underreporting of the disease (given clinical similarity to meningococcemia), and potential rapid acquisition of immunity in a previously nonimmune population.[22] No explanation completely accounts for the unusual disease pattern, and investigations into the pathogenesis of BPF continue.

Potential virulence factors of BPF strains include lipooligosaccharides, capsular polysaccharides, pilus proteins, immunoglobulin A proteases, membrane-associated proteins, and extracellular proteins.[23] BPF strains express both pilus and nonpilus adhesins that presumably facilitate mucosal colonization.[24] Compared with non-BPF strains, BPF strains resist lysis after incubation with normal adult human serum[25] and are cytotoxic for microvascular endothelial cells.[26] Additionally, BPF strains produce an extracellular hemagglutinating protein purported to be responsible for the hemorrhagic manifestations of BPF.[27] Horizontal transfer of virulent genes from *Neisseria meningitidis* to *H. influenzae* recently has been described, and this type of genetic acquisition also may play a role in pathogenic potential of *H. influenzae* biogroup *aegyptius*.[28]

Early systemic antibiotic therapy can improve clinical outcome in patients with BPF. Appropriate therapeutic options include ampicillin, chloramphenicol, cefotaxime, or ceftriaxone; most isolates of the BPF clone are resistant to trimethoprim-sulfamethoxazole.[10] In a randomized trial of children with *H. influenzae* biogroup *aegyptius* conjunctivitis, systemic therapy with rifampin (20 mg/kg orally once daily for 4 days) eradicated the organism in 12 of 12 children, compared with only 7 of 16 children treated with topical chloramphenicol 0.5%.[29] This finding led to speculation that oral rifampin might prevent development of BPF.

Haemophilus ducreyi

H. ducreyi is the causative agent of chancroid, a sexually transmitted infection characterized by genital ulceration and inguinal adenitis.[30] Described by Ducrey in 1889, *H. ducreyi* is a fastidious coccobacillary gram-negative bacterium that requires X factor for growth. Studies of DNA homology and ribosomal RNA gene sequences indicate that, although *H. ducreyi* is correctly assigned to the family Pasteurellaceae, classification in the genus *Haemophilus* should be reconsidered.[31,32]

Chancroid occurs sporadically in developed countries but is a major cause of genital ulcer disease in developing countries.[30] In the U.S., chancroid usually occurs in discrete outbreaks, and reported cases increased markedly during the 1980s to a high of 5001 cases in 1988. Since then, reported cases have declined steadily, with only about 300 reported cases from 2000 to 2007, <50 cases per year since 2004, and only 8 cases reported in 6 states in 2011.[33] Poverty, sex for money or drugs, and illicit drug use are well-recognized risk factors. Chancroid is an important cofactor in the transmission of human immunodeficiency virus (HIV). In addition, as many as 10% of patients with chancroid have syphilis or herpes simplex virus (HSV) infection.[34]

Transmission of *H. ducreyi* occurs through sexual contact, putatively gaining tissue entry through epithelial microabrasions. After an incubation period of 3 to 10 days, a papule develops. Papules, typically surrounded by erythema, evolve over 2–3 days into pustules that ultimately rupture to form tender, friable, sharply circumscribed ulcers with grey or yellow purulent exudates. Without therapy, ulcers usually resolve only after several weeks or months. In advanced cases, however, scarring can occur despite appropriate therapy.[35] Chancroid occurs more frequently in men than women. Depending on the locations of ulcers, women can have subtle symptoms such as dysuria, dyspareunia, vaginal discharge, dyschezia, or rectal bleeding. Rarely, extragenital lesions occur. About 50% of patients develop painful, tender enlarged inguinal lymph nodes, which can become fluctuant and, if not aspirated or drained surgically, rupture spontaneously. Occasionally, ulcers can appear and resolve, with development of suppurative inguinal adenitis 1–3 weeks later.[30]

Recently, *H. ducreyi* was newly recognized as a cause of chronic skin ulcers in children. Two studies, primarily of children with nongenital skin ulcers in Papua New Guinea, identified *H. ducreyi* as the causative agent for a large proportion of these lesions.[36–38] Compared with yaws, *H. ducreyi* ulcers tended to be more shallow and painful and more commonly are found on the lower extremities.[38]

Although the pathogenesis of *H. ducreyi* infection is incompletely understood, several potential virulence factors have been described.[39–45] These include lipooligosaccharide,[42–45] pili,[46] soluble cytolethal distending toxin,[47–49] hemoglobin-binding outer membrane protein,[50,51] cytotoxic hemolysin,[52,53] copper-zinc superoxide dismutase,[54,55] filamentous hemagglutinin-like protein,[56] and zinc-binding periplasmic protein.[57] In addition, two proteins that likely facilitate *H. ducreyi* persistence within genital epithelium are HgbA, which mediates hemoglobin binding,[58] and Dsr, which mediates serum resistance.[59–61]

In the US, the most common causes of genital ulcer disease in sexually active patients are HSV infection, syphilis, and chancroid. In developing countries, the differential diagnosis also includes granuloma inguinale and lymphogranuloma venereum.[62] Definitive diagnosis of chancroid requires recovery of *H. ducreyi* on special culture media, which often is not available readily. Even under optimal conditions, culture sensitivity is <80% compared with polymerase chain reaction testing; however, no US Food and Drug Administration–approved polymerase chain reaction test for *H. ducreyi* exists currently.[62] Direct Gram stain examination of clinical material can be misleading and is not recommended as a diagnostic test.[30,63] The diagnosis of chancroid, therefore, is based on clinical findings and the exclusion of other causes of genital ulcers.[34] Current guidelines from the Centers for Disease Control and Prevention indicate that diagnosis of a probable chancroid can be made in a patient with all of the following features: (1) one or more painful genital ulcers; (2) no evidence of syphilis (i.e., by darkfield examination of ulcer exudate *or* serologic testing performed ≥7 days after onset of ulcers); (3) clinical presentation, appearance of genital ulcers and, if present, regional lymphadenopathy; and (4) a negative test for HSV performed on the ulcer exudate.[62]

Effective antibiotic regimens in the treatment of chancroid include ceftriaxone (250 mg) as a single dose intramuscularly, azithromycin (1 g) as a single dose orally, ciprofloxacin (500 mg) twice daily for 3 days orally, and erythromycin base (500 mg) thrice daily for 7 days orally.[62] Worldwide, intermediate resistance has been noted to either ciprofloxacin or erythromycin.[62] HIV-infected patients who receive single-dose ceftriaxone or azithromycin therapy should be monitored closely because data are limited regarding efficacy of these regimens in this population.[62] Patients should be re-examined 3 to 7 days after initiation of therapy. If therapy is successful, symptoms improve within 3 days and ulcers begin to resolve objectively after 7 days. Possible reasons for therapeutic failures include incorrect diagnosis, coinfection with another sexually transmitted infection, coinfection with HIV, nonadherence to therapy, and infection with an *H. ducreyi* strain resistant to the prescribed antimicrobial agent. Large ulcers may not heal completely for >2 weeks. Fluctuant lymph nodes may require needle aspiration or incision and drainage despite otherwise successful medical therapy. Uncircumcised men and patients with HIV infection do not respond as well to treatment as do those who are circumcised or not infected with HIV.[62] Patients with chancroid should be evaluated for other sexually transmitted infections at the time of diagnosis and should be retested for syphilis and HIV infection 3 months later if initial test results are negative. Sex partners (i.e., contact within 10 days before symptom onset) of patients with chancroid should be examined and treated even if symptom free.[34,62]

Oral and Pharyngeal *Haemophilus* Species

Haemophilus spp. (including those reclassified as *Aggregatibacter* spp.) account for about 10% of the cultivable flora of the oral cavity and upper respiratory tract of healthy children. *H. parainfluenzae* comprises about three fourths of pharyngeal *Haemophilus* isolates. A recent study of children undergoing adenoidectomy found that 97% were colonized with *H. parainfluenzae* in the adenoid core; biofilm formation was identified as having a potential role in chronic adenoiditis.[64] Nonencapsulated *H. influenzae,* although present in 80% of healthy children, makes up <2% of total pharyngeal flora.[65] *Aggregatibacter* spp. (formerly *H. aphrophilus, H. paraphrophilus,* and *H. segnis*) are found especially in dental plaque specimens in adults, and *H. haemolyticus* is recovered primarily from gingival crevices.[1,65] Additionally, *H. parainfluenzae* and *H. influenzae* occasionally are isolated from urethral and vaginal specimens from adults and children.[66,67] On rare occasions, these commensals can cause disease. Infections most consistently associated with *H. parainfluenzae* in children are endocarditis and meningitis[68,69]; however, it is possible that *H. influenzae* isolates that were misidentified as *H. parainfluenzae* account for many of the reported meningitis cases.[1,69] Other pediatric infections reportedly caused by *H. parainfluenzae* include bacteremia; septic arthritis; urinary tract infection; peritonitis; abscesses of the liver, brain, and soft tissue; and head and neck infections.[68–72] Historically, *A. aphrophilus* (formerly *H. aphrophilus*) was associated with a similar spectrum of diseases in children, along with rare cases of cervical lymphadenitis[73–77] Bacteremia and secondary brain abscesses have been associated with recent dental work, including one pediatric case after manipulation of dental braces.[78] *A. aphrophilus* (formerly *H. paraphrophilus*) has been reported in children to cause epiglottitis,[79] fatal pneumonia,[80] septic arthritis,[81] and intracerebral abscess.[82] *H. parahaemolyticus* was reported to cause periorbital cellulitis in a toddler.[83] *H. haemolyticus* frequently colonizes the oropharynx of children with bronchiectasis, the significance of which is unclear.[84] Recently, using multilocus sequence analysis, *H. haemolyticus* (misidentified as *H. influenzae*) was found to cause bacteremia in a 1-year-old child, suggesting a possible role in invasive infections more frequently than recognized previously.[85] *A. segnis* (formerly *H. segnis*) has not been described as a pediatric pathogen.

Haemophilus spp. (now including *Aggregatibacter* spp.) cause approximately 3% to 5% of cases of infective endocarditis in adults[86] and children.[87,88] A literature review of cases reported between 1965 and 2001 identified 17 pediatric cases of *Haemophilus* spp. endocarditis; etiologic agents were *H. parainfluenzae* in 13 cases and *A. aphrophilus* in 4 cases. Of these cases, 10 had underlying cardiac abnormalities, 8 suffered embolic complications, 6 required cardiac surgery, and 2 died.[72] *A. aphrophilus* endocarditis is more common in patients with congenital heart disease but can occur in structurally normal hearts.[89] *A. paraphrophilus*, which is a rare cause of endocarditis in adults, has not been reported in children.

Ampicillin remains the drug of choice for infections caused by ampicillin-susceptible *Haemophilus* spp. Ampicillin resistance due to β-lactamase production or alterations in penicillin binding proteins can occur.[1] In studies from southern Europe, 10%–57% of respiratory *H. parainfluenzae* isolates produced β-lactamase; moreover, 40% were resistant to trimethoprim-sulfamethoxazole, and 40% were resistant to clarithromycin. Additionally, there are isolated reports of extended-spectrum β-lactamases–mediated resistance, as well as high-level fluoroquinolone–resistant *Haemophilus* spp.[90,91] A case report from Switzerland in 2013 described the first cases of extensively drug-resistant *H. parainfluenzae*.[92] Because antimicrobial susceptibility testing has not been well standardized for *A. aphrophilus,* rates of resistance are unknown. For treatment of serious infections caused by *Haemophilus* spp. and *A. aphrophilus*, cefotaxime or ceftriaxone should be administered intravenously until antibiotic susceptibility test results are available. For uncomplicated native valve endocarditis, the minimal duration of antimicrobial therapy is 4 weeks.

Helicobacter pylori

Luis A. Castagnini, Benjamin D. Gold, Mark A. Gilger

Helicobacter pylori infection is ubiquitous among humans. Moodley and colleagues estimated that *H. pylori* has infected humans for >80,000 years.[1,2] Despite declining prevalence in developed countries, *H. pylori* continues to be one of the most common human infections worldwide.[3] Different sources of infection have been suggested, including contaminated water and contact with soil, but person-to-person transmission seems to be the primary mechanism through fecal-oral, oral-oral, and gastro-oral routes during early childhood.[4–7] Although a number of zoonotic mechanisms for transmission have been postulated, nonhuman reservoirs have not been demonstrated definitively. *H. pylori* infection causes gastritis, duodenal and gastric ulcers, as well as gastric adenocarcinoma and mucosa-associated lymphoid tissue (MALT) lymphoma. *H. pylori* also has been associated with extragastric conditions, including growth failure, iron deficiency anemia, cardiovascular diseases, and chronic idiopathic thrombocytopenia purpura (ITP). Bacterial virulence, host factors, and potentially environmental exposures play a role in determining the type of gastroduodenal inflammation that occurs and in *H. pylori* disease outcome.[8,9] Evidence-based clinical practice guidelines published in 2011 recommend eradication of *H. pylori* in infected children if there are primary family members with gastric cancer or in patients with peptic ulcer disease, but discourages the “test and treat” approach.[10]

The Pathogen

H. pylori is a gram-negative, motile, flagellated spiral-shaped bacillus that resides in the human gastric mucosa. It is S shaped in vivo and measures up to 5 μm long. Numerous studies provide evidence of colonization of the oral cavity, and a meta-analysis demonstrated a close relationship between the presence of *H. pylori* in the oral cavity and stomach and suggested the oral cavity may be a source of reinfection.[11–14]

The pattern of gastric mucosal colonization by *H. pylori* and resultant gastric inflammation appears to play a major role in influencing disease phenotype.[15–17] In 2005, the Nobel Prize in Medicine was awarded for the 1982 discovery of *H. pylori* (then called *Campylobacter pyloridis*) and its association with duodenal and gastric ulcer disease.[18] *Helicobacter* constitutes group III of the rRNA superfamily VI, which also includes *Campylobacter* (group I) and *Arcobacter* (group II).[19–22] A number of *Helicobacter* species have been identified, with *H. pylori* being the most common and the primary pathogen associated with human disease.[23–25] *H. pylori* has been isolated from primates (previously called *Helicobacter nemestrinae*), but no conclusive evidence exists of animal-to-human transmission.[26]

H. pylori is a microaerophilic bacterium able to successfully overcome the adversity of the acidic gastric mucosa owing to its unique properties, including spiral shape, motility, and production of significant quantities of urease. Other virulence factors include the production of catalase, oxidase, mucinase, and a vacuolating cytotoxin (VacA), but the role of these on disease severity or progression is unclear. *H. pylori* urease is a potent stimulus for memory CD8$^+$ T lymphocytes, which show a 15-fold greater response to urease in infected compared with uninfected subjects, and might have important implications for development of more severe disease.[27,28] Much attention has been focused on a portion of the *H. pylori* bacterial genome called the *cytotoxin-associated gene pathogenicity island*, which contains genes responsible for disease outcomes in the infected host.[19,29–32] Genetic variability is the rule with *H. pylori,* and these genetic modifications have led investigators to label variant strains a type of "quasi-species."[33–35]

H. pylori infection elicits a variety of phenotypic responses in cultured gastric epithelial cells, including the expression of proinflammatory genes and changes in the actin cytoskeleton. Both responses are mediated by the type IV secretion system (TFSS) encoded by the *cag* pathogenicity island (*cag* PAI) that contains more than 31 genes.[21,28,36] TFSS is unique among bacteria species and is postulated to be a key mechanism in *H. pylori*–associated carcinogenesis.[32] In addition, blood group antigen-binding adhesin BabA-mediated binding of *H. pylori* to Lewis blood group b antigen (Le^b) on the epithelial surface augments TFSS-dependent *H. pylori* pathogenicity by triggering the production of proinflammatory cytokines and precancer-related factors.[37] *H. pylori* adheres intimately to epithelial cells in the gastric mucosa and expresses several surface proteins, including a blood group antigen-binding adhesin, BabA.[38–40] Lewis-associated antigens, carbohydrates related biochemically to the ABO blood groups, also are thought to play a role in *H. pylori* adhesion to gastric mucosa. *H. pylori* is one of the few known microbes to be able to use its host glycoproteins (i.e., Le^x and Le^y antigens) within its outer membrane to facilitate immune evasion. Moreover, *H. pylori* contains a fucosyltransferase gene (*α1,3,4-FUT*) expressed in the bacterial outer membrane as lipopolysaccharide moieties strikingly similar to Le^x and Le^y epitopes, which facilitates the persistence in colonization and immune cell evasion.[37,38,41,42]

Epidemiology

H. pylori resides in the stomach of more than 50% of the world's population, making it the most common chronic infection worldwide. Prevalence varies by geographic area, age, race, and socioeconomic status. In developed countries, <40% of the population might be infected.[3] However, in developing countries or populations with poor water and sanitation conditions (e.g., Native Canadians and Native Alaskans), up to 90% of the population is infected.[43,44] Socioeconomic status has an inverse relation with the prevalence of infection and is one of the most important risk factors for acquisition.[45] In poor populations, infection usually is acquired early in children <10 years of age.[43–47]

A large study in Amazonian natives found an overall *H. pylori* seroprevalence of 92%, with >80% of children positive by 3 years of age; interestingly, infection did not correlate with the length of contact with the outside world, suggesting that *H. pylori* was indigenous.[48] In contrast, several studies suggest *H. pylori* seroprevalence has decreased worldwide since the 1960s, with greater declines in developed countries and overall seroprevalence of <15% by 10 years of age (Fig. 174.1).[45,49–54] The reasons for declining prevalence is unknown, although better living conditions, less crowding, smaller family size, clean and chlorinated water, and the widespread use of antibiotics might have contributed.[55,56] Some researchers have speculated that (1) not all *H. pylori* strains are pathogenic, (2) at some point *H. pylori* may have been part of the human gastrointestinal microbiome, and (3) changes in the prevalence of *H. pylori* infection might have implications for human health.[57–63]

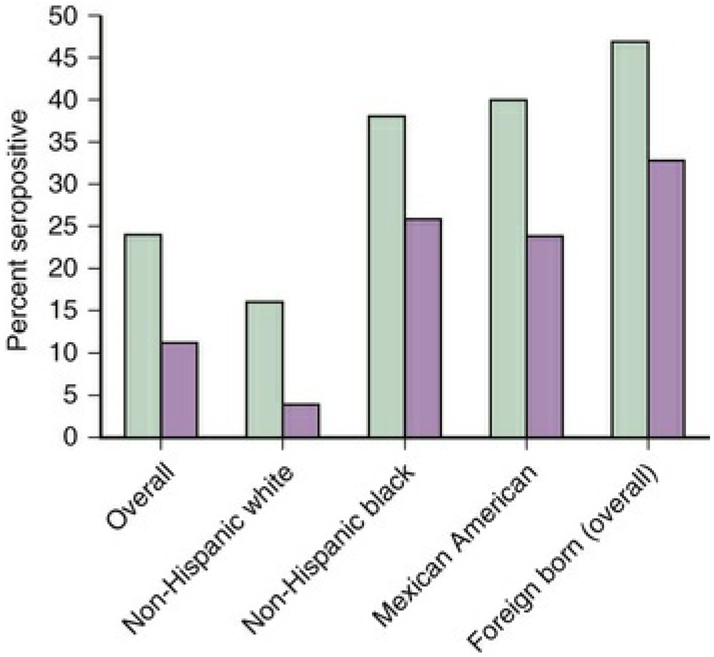

FIGURE 174.1 Declining seroprevalence of *Helicobacter pylori* in US children, using sera from NHANES III (1988–1991) (*pale blue bars*, 2795 subjects) and NHANES (1999–2000) *(purple bars,* 2898 subjects). Change in seroprevalence over time periods has P < 0.001. (Redrawn from Gold BD, Kruszon-Moran D, Sobel J, et al. Decreasing seroprevalence of *Helicobacter pylori* infection in U.S. children ages 6–19 years. J Pediatric Gastroenterol Nutr 2003;37:360.)

Most new *H. pylori* infections are acquired during childhood, especially in developing countries.[56,64–67] Up to half of all children in Chile, Portugal, Nigeria, and Bangladesh are infected during their first 5 years of life.[68–71] Turkish children acquire *H. pylori* infection 2.5 times more often than they discard infection[72]; after eradication of infection, children, particularly adolescents, become reinfected more frequently than adults. Close contact with children, especially siblings <5 years of age, could be a more important risk factor for recurrent infection than age at initiation of treatment.[73]

In the United States, ethnic differences are notable in the prevalence of *H. pylori* infection. African American and Hispanic populations, as well as immigrant populations, have a twofold to sixfold increased risk for seropositivity compared with white people of higher socioeconomic status.[48,52,53] Data from the National Health and Nutrition Evaluation Survey (NHANES) demonstrated that as many as 42% of Mexican Americans aged 6–19 years are infected compared with 40% of non-Hispanic blacks and 17% of non-Hispanic whites.[74] Overall, gender is not associated with prevalence of *H. pylori* infection but may play a role in the disease outcome.[75] Lower socioeconomic status and poor hygiene in the living environment, particularly during childhood, correlate with higher *H. pylori* prevalence.[44,46,76–79] A study of twins raised separately who were discordant for *H. pylori* infection found that affected twins were raised under poorer conditions compared with their unaffected cotwins.[80] Most data infer that the mother more than the father plays the predominant role in infection owing to overall higher contact with their infants and young children in whom acquisition primarily occurs.[44,81–83] Increased consumption of fruits and vegetables and vitamin C supplements reduces the probability of acquisition of *H. pylori* infection and the severity of disease outcomes.[84,85] Breastfeeding during infancy has not been found to be protective against *H. pylori* infection.[86,87]

H. pylori transmission occurs primarily from person to person, but waterborne and iatrogenic spread through contaminated medical equipment also have been described.[88–91] Person-to-person transmission includes fecal-oral, gastro-oral and oral-oral routes, with much higher risks associated with neurologically impaired persons residing in an institutionalized setting where close personal contact and exposure to feces and vomitus is frequent.[92–95] Multiple studies of families, some multigenerational, show increased risk for intrafamilial transmission, especially mother to offspring, younger to older sibling, and between spouses.[93,96–100] The risk for transmission to young children is estimated to be eightfold higher if the mother is infected and fourfold higher if the father is infected.[101] A number of studies demonstrated that *H. pylori* isolates from family members are homologous by DNA fingerprinting.[102–106]

The fecal-oral route is the predominant mode of transmission, and *H. pylori* DNA is detected in the stool of infected individuals by a variety of molecular methods.[106–108] DNA purification followed by *H. pylori* polymerase chain reaction (PCR) analysis is an effective tool for harvesting *H. pylori* DNA isolates from the feces of children, with positive and negative predictive values of 80% and 100%, respectively.[107] Primary isolation of *H. pylori* from stool is difficult, although some research-based laboratories have been able to recover the organism from up to 50% of infected persons.[64,95] Oral-oral transmission also can occur in certain populations; the organism has been found in saliva, dental plaque, reflux of gastric contents, and vomitus, and transmission might be associated with premastication of food by mothers.[44,95,109–114]

Although transmission through contaminated, poorly sanitized water is debated, the evidence is compelling.[115–122] Studies have isolated *H. pylori* from well water and sewage-contaminated water, and one study showed that children whose water source was outside their homes had infection rates threefold higher than children whose homes had an internal water source.[6,123–126] Transmission in the healthcare setting also is important, even in the developed world.[88,127] A meta-analysis reviewed 11 cross-sectional and 3 prospective studies that evaluated the occupational risks of healthcare personnel for acquisition of *H. pylori*.[127] The risks are highest for gastroenterologists, some nurses, and employees caring for persons with mental disability; however, results for other groups are conflicting.[88,128] Moreover, the use of improperly disinfected endoscopes increases the risk for infection, whereas disinfection of endoscopes by soaking in glutaraldehyde cleaning agents and, more important, cleansing of the channels by vigorous brushing reduces the risk for *H. pylori* acquisition.[88,129]

Pathogenesis

H. pylori infection and its long-term effects, including peptic ulcer, MALT lymphoma, and gastric adenocarcinoma, result from a complex interaction between the organism's virulence factors, susceptibility and immunologic response of the host, and environmental factors that might modulate susceptibility to infection, disease, or both.[17,130–133] Pathogenesis and natural history are depicted in Fig. 174.2. Several mechanisms have been elucidated that allow the pathogen to persistently colonize the gastric epithelium, generate mucosal inflammation, and regulate gastric acid output, subsequently causing a wide spectrum of chronic ailments.

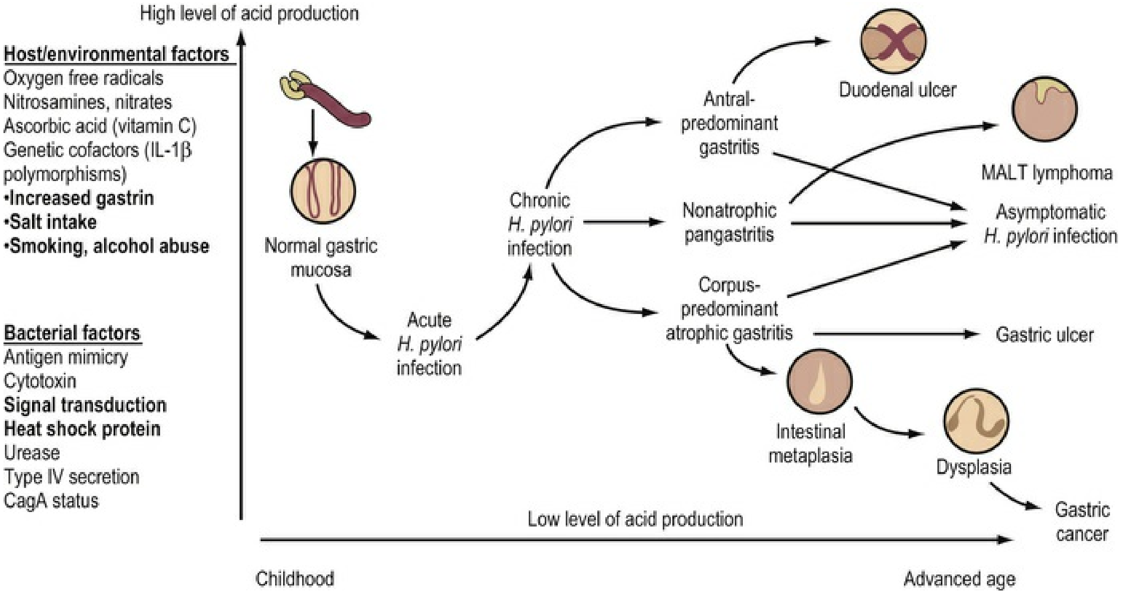

FIGURE 174.2 Pathogenesis and natural history of *Helicobacter pylori*. Bacterial, host, and environmental determinants affect disease outcome. MALT, mucosa-associated lymphoid tissue. (Modified from Suerbaum S, Michetti P. *Helicobacter pylori* infection. N Engl J Med 2002;347:1175–1186.)

H. pylori produces high quantities of urease enzyme, which converts urea into ammonium and bicarbonate, thereby creating an alkaline microenvironment that permits survival despite gastric acidity.[134,135] Colonization of gastric mucosa is initiated by a unique and specific tropism for gastric epithelial cells rich in Le^b blood group antigen with attachment mediated by the bacterial blood group antigen-binding adhesin BabA.[37,38,136–140] Although other bacterial adhesins may contribute to colonization, expression of BabA has been associated with duodenal ulcer and gastric adenocarcinoma.[38,139] The vacuolating cytotoxin VacA also is associated with an increased risk for gastroduodenal ulcers and, to a lesser extent, gastric cancer.[141–143] Polymorphisms, and the two main variable regions of the *vacA* gene, the signal sequence (*s*) and the mid region (*m*) properties, facilitate typing of isolated strains.[144] Expression of these regions reflects production of the vacuolating toxin; s1-m1, s1-m2, and s2-m1 genotypes correspond to high, medium, and low toxin-producing strains, respectively. However, the overall correlation between *vacA* and disease phenotype remains equivocal.

H. pylori is a potent inducer of gastric mucosal inflammation through various mechanisms, the most important of which is CagA.[145–147] TFSS are macromolecular assemblies, which are widespread in pathogenic bacteria, and often are used to deliver effectors into host cells. Encoded for in the *cag* PAI, *H. pylori* encodes Cag TFSS that mediates the injection of the toxin CagA into gastric epithelial cells, where it undergoes tyrosine phosphorylation by host cell kinases.[37,148] CagA then activates nuclear factor κB (NF-κB), the intracellular signaling pathway that regulates induction of the proinflammatory cytokines interleukin-8 (IL-8) and IL-1β.[149,150] The relative ability of *H. pylori* strains to induce epithelial cell inflammation is dependent on the presence of an intact *cag* PAI containing the *picB* gene.[151] Strains that possess the complete PAI induce pangastritis, which evolves to gastric ulceration, atrophy, intestinal metaplasia, and eventually, distal gastric cancer.[151] *CagA*$^+$ variant strains that have an incomplete *cag* PAI (because of deletions or mutations) induce antral-predominant gastritis, more likely leading to duodenal ulcer than to distal gastric cancer.[32,151]

H. pylori strains that possess toxigenic *vacA s1* allele, a complete *cag* PAI, *cagA* alleles containing multiple EPIYA phosphorylation sites, and expression of BabA adhesin, correlates with development of gastroduodenal disease in adults. In a study involving 47 North American children with a variety of gastroduodenal pathologies, a range of EPIYA motif configurations were observed for the *cagA* gene, which was present in strains from 47% of patients, but only 41% contained a complete *cag* PAI. Sixty-four percent of children were infected with a strain having the *vacA s1* allele, and 60% had the *babA* gene. The presence of a functional *cag* PAI had a significant correlation with ulcer disease.[152] Pediatric strains differ in their spectrum of strain-variable genes and percentage of absent genes compared with adult strains. Moreover, in this novel study, most children were infected with *H. pylori* strains lacking the *cag* PAI, but the presence of a complete *cag* PAI (in contrast to other virulence markers) was associated with more severe gastroduodenal disease.[152] Although *H. pylori* strains that possess the *cag* PAI and secrete a functional cytotoxin induce more severe gastric injury and further augment the risk for developing distal gastric cancer, carcinogenesis also is influenced by host genetic diversity, particularly involving immune response genes such as *IL-1β* and *TNF-α* as well as expression of tumor suppressor genes, including *p53* and *c-myc*.[153]

H. pylori urease binds to major histocompatibility complex class II molecules expressed on the surface of gastric epithelial cells, which in turn induces apoptosis and thus modulates cell growth.[154–156] A second mechanism is the induction of Fas-Fas ligand–regulated apoptosis through two different proinflammatory cytokines: (1) production of interferon γ (IFNγ) induced by a Th1 immune response triggered by *H. pylori* colonization and (2) induction of IL-1β by CagA.[157-159] CagA is one of the primary *H. pylori*–produced stimuli of production of the proinflammatory cytokine IL-1β, which also is a potent inhibitor of gastric acid secretion.[133,160,161] Gastric acidity may be further reduced in *H. pylori*–infected individuals with particular polymorphisms of the IL-1β gene promoter, thereby increasing the risk for atrophic gastritis and gastric adenocarcinoma.[161,162] Another virulence marker of *H. pylori* is the *iceA* gene, so called because its expression is induced after contact with epithelial cells.[143] The gene has two distinct genotypes, *iceA1* and *iceA2,* but the overall relevance of genotypes to disease phenotype remains unclear.[163–166]

Although more than 50% of the world's population is infected, most individuals remain clinically asymptomatic, suggesting that not all *H. pylori* strains are pathogenic. It is not clear why 15% to 20% of infected people develop gastroduodenal ulcer disease and <1% develop gastric adenocarcinoma.[17,167] Identifying markers that predict more severe disease outcomes is of great importance to implement cost-effective public health strategies to target eradication treatment efforts. In both children and adults, studies to determine associations between BabA, VacA, CagA, and PicB with peptic ulcer and gastric cancer continue to reveal conflicting results.[37,39,40,165,166] Although *cag* PAI appears to be the one marker of inflammation and clinical disease found in clinical isolates of *H. pylori,* other virulence factors appear to be markers of geographic distribution rather than predictors of disease outcome (see Fig. 174.2).[163,168,169]

Clinical Manifestations

Intestinal Disease

H. pylori infection in children generally is asymptomatic. However, when there is persistent colonization, gastritis develops almost universally. Although there are a number of reports of spontaneous elimination of *H. pylori* infection in children, many of these studies are limited by the methodology used to detect infection.[46,170–172] The association between *H. pylori* infection and gastritis and duodenal ulcer disease in children is very strong.[173–175] The rate and mechanism of spontaneous clearance of infection in children is not known. Nodular gastritis appears to be observed more commonly in children (Fig. 174.3); however, the time to development of endoscopically visible nodules and their natural history remains uncharacterized.[176–179] Additionally, it is not clear which children with lymphofollicular gastritis will progress to develop MALT lymphoma, and over what time period.[180,181] Studies have demonstrated that eradication of *H. pylori* in children with MALT lymphoma results in resolution of the mucosal disease, both gastric and extragastric.[181,182]

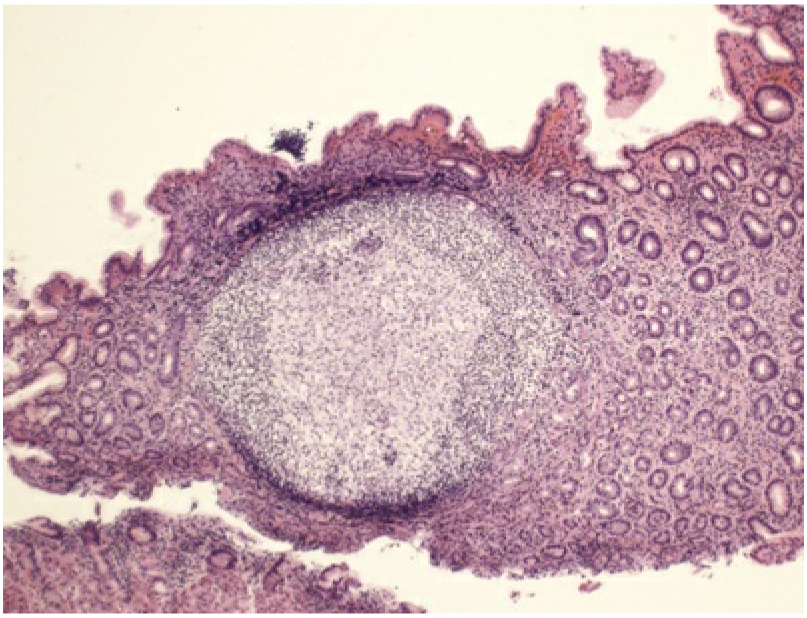

FIGURE 174.3 Large lymphoid nodule in inflamed antrum (hematoxylin-eosin stain; original magnification, ×50). (Courtesy of Dr. Milton Finegold, Department of Pathology, Baylor College of Medicine, Texas Children's Hospital.)

Although individual cases and case series of gastric adenocarcinoma and MALT lymphoma have been reported in the pediatric population, these conditions are rare in children.[181,183–185] However, early childhood acquisition and persistence of *H. pylori* significantly increase the risk for gastric malignancies in adults.[186,187] Atrophic gastritis and intestinal metaplasia, precursor lesions for gastric cancer, occur in *H. pylori*–infected children.[188,189] In a study of 173 children from countries with high incidence of gastric cancer, atrophic gastritis was noted in 16% of those with active *H. pylori* infection.[189] Atrophic mucosa was seen as pseudopyloric metaplasia (63%), intestinal metaplasia (31%), or both (6%). Investigators also suggested that identification of this specific disease phenotype requires targeted biopsies to include the lesser and greater curve of the gastric corpus, in addition to biopsies targeting the antrum and cardia.[189]

Landmark studies demonstrated that *IL-1* gene cluster polymorphisms leading to increased IL-1β production are associated with an increased risk for *H. pylori*–induced hypochlorhydria and gastric cancer.[8] Compared with healthy controls, relatives of patients with gastric cancer had a higher prevalence of hypochlorhydria (27% vs. 3%) despite having a similar prevalence of *H. pylori* infection (63% vs. 64%).[162,190]

Relatives of cancer patients matched for *H. pylori* prevalence also had a higher prevalence of atrophy (34%) than patients with nonulcer dyspepsia (5%). Increased prevalence of precancerous gastric abnormalities in relatives is limited to those with *H. pylori* infection. These findings prompted changes in current pediatric guidelines to target prophylactic eradication and prevention strategies to selected patients, especially those with a first-degree relative with gastric cancer.[10,191]

Although a relationship between ulcer disease and abdominal symptoms is apparent, it is unclear whether chronic gastritis causes symptoms in children. Results from studies around the world have been conflicting, precluding a definitive recommendation for treatment of *H. pylori* found in the child with gastrointestinal symptoms but no demonstrable disease. Some studies have reported an association of *H. pylori* infection with recurrent abdominal pain in children; however, it is difficult to reach definite conclusions from these studies given some methodologic flaws, including lack of randomization, lack of double blinding, absence of a validated symptom assessment instrument, and no assessment of the socioeconomic status as a confounding variable.[192–196] One population-based cross-sectional study that evaluated the relationship between *H. pylori* infection, recurrent abdominal pain, and social and familial factors in 1221 children aged 5–8 years showed an association between abdominal pain and social and familial factors but not between abdominal pain and *H. pylori* infection.[197] Other studies have confirmed these findings.[198,199] In a well-designed randomized placebo-controlled treatment trial of 20 children with *H. pylori* infection, gastritis, and recurrent abdominal pain, 8 of 10 in the treatment group had eradication of *H. pylori* compared with 0 of 10 in the placebo group. However, at 52 weeks, bacterial eradication and healing of gastric inflammation did not lead to relief of chronic abdominal pain.[200] Epigastric pain, abdominal pain causing nocturnal wakening, hematemesis, and recurrent vomiting are not associated with *H. pylori* infection, and no difference in frequency was found between colonized and noncolonized children.[192]

The true incidence of gastric and duodenal ulcer disease in children is unknown. However, children with duodenal or gastric ulcers have symptoms similar to those of adults, including sharp, burning pain in the epigastrium that generally occurs with an empty stomach, between meals, and during the early morning hours. In addition, signs of occult or frank bleeding can occur. Primary ulcers in the pediatric population (most of which are *H. pylori* associated) occur in the duodenum and are seen in older children. Gastric ulcers are less common and usually are secondary (i.e., due to another disease process such as Crohn disease or produced by chemical irritation of the gastric mucosa as caused by aspirin or nonsteroidal anti-inflammatory drugs).[201]

Whether *H. pylori* infection predisposes to or provides protection against diarrheal diseases in children remains a topic of debate. A number of studies provide compelling evidence that *H. pylori* −infected children are more at risk for diarrhea due to enteric infections.[202,203] For example, a study in Peru showed a high incidence of diarrhea in children with *H. pylori* infection, probably as a result of the transient achlorhydria that occurs during the acute phase of infection.[203] Increased rates of enteric infection in the face of early *H. pylori* infection likely are due to poor water sanitation or poor hygiene, resulting in increased exposure to enteric pathogens. Conversely, others studies have shown a protective effect of *H. pylori* infection against diarrheal diseases.[204–206] These conflicting observations may be explained by factors related to the age and socioeconomic status of the population studied, the geographic region in which the child resides, or the stage at which infection is detected because protection against diarrhea occurs when the pH returns to acid. Furthermore, the presence of *H. pylori* augments the local and systemic immune response to enteropathogens, as has been demonstrated in *Vibrio cholerae*.[207,208]

The controversy surrounding whether *H. pylori* infection is protective, causative, or unrelated to gastroesophageal reflux disease (GERD) in adults and children has for the most part been settled. *H. pylori* at most is an innocent bystander and is not protective against GERD or its sequelae in both children and adults.[48,209,210] Although there is reverse prevalence of GERD in countries with a high and low prevalence of *H. pylori,* conclusion of causality is overly simplistic.[211] In a study of 95 children and adolescents who were recruited and completed an eradication trial with a mean follow-up of 11.2 months, the distribution of outcomes for each GER symptom (better, worse, unchanged) was similar before and after eradication and did not depend on prior *H. pylori* status.[212] These data and other case series prompted guideline committees to recommend *H. pylori* eradication in children with GERD who are undergoing endoscopy.[10,191] However, when the diagnosis of GERD is made clinically or by pH monitoring, it is not necessary to screen for *H. pylori*.

Extraintestinal Disease

Multiple reports from around the world have demonstrated an association between *H. pylori* infection and iron deficiency anemia.[213–216] In the US NHANES survey for 1999–2000, *H. pylori* infection was associated with iron deficiency and iron deficiency anemia in 7462 survey participants 3 years or older. *H. pylori* infection also was associated with decreased serum ferritin levels, but not with levels of free erythrocyte protoporphyrin, transferrin saturation, or hemoglobin. Although multicenter, sufficiently powered, randomized controlled treatment trials have not been performed, evidence suggests that anemia and iron deficiency may benefit from *H. pylori* eradication.

The first reports of *H. pylori* infection effects on growth retardation were published from Gambia and demonstrated convincingly that *H. pylori* could be a cofactor for growth disturbance in children infected early in life.[217] Longitudinal studies in children have demonstrated a link between short stature and *H. pylori* infection, especially in girls, although the association of infection with failure to thrive needs further study.[218,219] In a large Colombian cohort study, among 105 children who were infected with *H. pylori*, a significant decrease in growth velocity was observed during the first 4 months after infection, without height catch-up in infected children. At 8 months after acquisition, an infected child had a cumulative difference of 0.24 cm (growth velocity) compared with uninfected children.[220] Likewise, in a Turkish study involving more than 3000 school-aged children, growth retardation was associated with *H. pylori* infection, independent of their poor living conditions.[221] Other studies have reached similar conclusions.[222–224] In at-risk populations, potential interventions that target infected preschool-aged children are likely to prevent growth retardation.

The role of *H. pylori* in idiopathic thrombocytopenic purpura (ITP) was first suggested in 1997.[225] Subsequent studies in adults have supported this initial observation.[226–229] In case series, eradication of *H. pylori* has been associated with platelet recovery in adults and children with ITP.[229,230] In a study of 17 children with ITP, *H. pylori* infection was not found.[231] In contrast, another investigation that used polyclonal *H. pylori* antigen stool testing found *H. pylori* infection in 9 of 22 children with ITP; after eradication therapy, 5 of these 9 children had increased platelet counts that persisted throughout the 24-month follow-up period.[227] Overall, eradication of *H. pylori* has been associated with remission of ITP in approximately half of patients. In a larger multicenter study in Italy, of 244 screened patients younger than 18 years with chronic ITP, 50 (20%) had *H. pylori* infection, 37 of whom received eradication therapy and completed follow-up. Eradication was successful in 89%; platelet recovery occurred in 39% of patients after eradication, whereas spontaneous remission occurred in 10% of *H. pylori*–negative patients ($P < 0.01$).[232] Screening and treatment for *H. pylori*-positive adults with ITP has been suggested.[233] Further controlled studies in children are needed.

Other clinical conditions that also have been associated with *H. pylori* infection include protein-losing gastropathy, periodontal disease, rosacea, food allergy, coronary artery disease, diabetes mellitus, neurologic disorders, and autoimmune diseases. However, these associations remain speculative.[234,235]

Diagnosis

There are no specific signs or symptoms that predict the presence of gastritis or peptic ulcer in children. Furthermore, most *H. pylori* infections and associated gastritis remain asymptomatic. However, children with warning symptoms or alarming signs, such as severe chronic abdominal pain, anorexia and failure to thrive, or persistent vomiting, require investigation. The presence of occult blood in feces, particularly in the face of iron deficiency anemia, should lead to investigation. The severity of symptoms determines the need for endoscopy; endoscopy and biopsy are performed to determine the cause of symptoms, not merely to investigate for *H. pylori* infection.[10,191] Management guidelines from the Canadian *H. pylori* study group and the European Society for Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) and North American Society for Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) are summarized in Table 174.1.[10,191]

TABLE 174.1

Management Guidelines for *Helicobacter pylori* in Children

Canadian *H. pylori* Study[a]	**ESPGHAN-NASPGHAN**[b]
Population-based screening for *H. pylori* in asymptomatic children to prevent gastric cancer is not warranted. Testing for *H. pylori* in children should be considered if there is a family history of gastric cancer. The goal of diagnostic interventions should be to determine the cause of presenting gastrointestinal symptoms and not the presence of *H. pylori* infection. Recurrent abdominal pain of childhood is not an indication to test for *H. pylori* infection. *H. pylori* testing is not required in patients with newly diagnosed GERD. *H. pylori* testing may be considered before the use of long-term proton pump inhibitor therapy. Testing for *H. pylori* infection should be considered in children with refractory iron deficiency anemia when no other cause has been found. When investigation of pediatric patients with persistent or severe upper abdominal symptoms is indicated, upper endoscopy with biopsy is the investigation of choice. The UBT currently is the best noninvasive diagnostic test for *H. pylori* infection in children. There is insufficient evidence to recommend stool antigen tests as acceptable diagnostic tools for *H. pylori* infection. *H. pylori* serologic antibody tests are not recommended as diagnostic tools for infection in children	The primary goal of clinical investigation of gastrointestinal symptoms is to determine the underlying cause of symptoms and not solely the presence of *H. pylori* infection. Diagnostic testing for *H. pylori* infection is not recommended in children with functional abdominal pain. In children with first-degree relatives with gastric cancer, testing for *H. pylori* may be considered. In children with refractory iron deficiency anemia, in which other causes have been ruled out, testing for *H. pylori* infection may be considered. For the diagnosis of *H. pylori* infection during EGD, gastric biopsies (antrum and corpus) should be obtained for histopathology. Initial diagnosis of *H. pylori* infection can be based on either positive histopathology plus positive rapid urease test or a positive culture. The UBT is a reliable noninvasive test to determine eradication of *H. pylori*. A validated EIA test for *H. pylori* antigen in stool is a reliable noninvasive test to determine eradication of *H. pylori*. Tests to detect antibodies (IgG, IgA) against *H. pylori* in serum, whole blood, urine, and saliva are not reliable for clinical use. Clinicians should wait at least 2 weeks after stopping PPI therapy and 4 weeks after stopping antibiotics to perform biopsy-based and noninvasive tests (UBT, stool test) for *H. pylori*.

ESPGHAN, European Society for Pediatric Gastroenterology, Hepatology and Nutrition; EGD, esophagogastroduodenoscopy; EIA enzyme immunoassay; GERD, gastroesophageal reflux; Ig, immunoglobulin; NASPGHAN, North American Society for Pediatric Gastroenterology, Hepatology and Nutrition; PPI, proton pump inhibitor; UBT, ^{13}C-urea breath test.

The gold standard for the diagnosis of *H. pylori* infection is identification of the organism in culture and histologic examination of gastric biopsy samples. Compared with histologic changes in adults, children have (1) a higher density of *H. pylori* within the pits and on the surface of epithelial cells and a milder degree of infiltration with neutrophils, plasma cells, and eosinophils; (2) similar degree of infiltration with mononuclear cells and atrophy; and (3) less frequent ulcers or intestinal metaplasia.[236,237] In children, mucosal ulceration is located in the duodenum and is uncommon in the gastric corpus, but it can be seen in the gastric antrum.[238] Hematoxylin and eosin staining of gastric secretions is not as sensitive as other stains (i.e., Warthin-Starry silver stain, acridine orange, or Giemsa stain). The sensitivity of hematoxylin and eosin staining of gastric secretions is 77% versus 88% for biopsy specimens taken by endoscopy (Fig. 174.4).[191,238] *H. pylori* is a fastidious organism; therefore biopsy material can be transported in saline only if it is to be processed within 3 hours—otherwise transport medium must be used, and the specimen should be kept on ice before inoculation. Gastric biopsy material can be tested using a rapid urease test that exploits the urease enzyme of *H. pylori* and can be performed in the endoscopy suite.[239] The entero-test is a noninvasive method to obtain a sample for culture for *H. pylori,* in which a capsule attached to a highly absorbent nylon string is swallowed. Amplification of several genes (urease, 16S RNA, 29-kd antigen, *cag,* and *vacA*) by PCR was demonstrated to be a successful alternative to culture and histology for diagnosis.[240,241] Although 16S RNA may be more sensitive for the detection of *H. pylori,* amplification of the *cag* or *vacA* genes gives more information on the infecting strain.[143,242,243] Biopsy specimens from the gastric antrum and corpus are inoculated onto enriched horse or sheep blood agar supplemented with antibiotics (vancomycin, amphotericin B, and cefoperazone) and incubated at 37°C in a microaerophilic atmosphere with 7% nitrogen. Isolation of *H. pylori* in culture provides the additional benefit of susceptibility testing; however, few clinical microbiology laboratories have the capacity to perform culture for *H. pylori*.

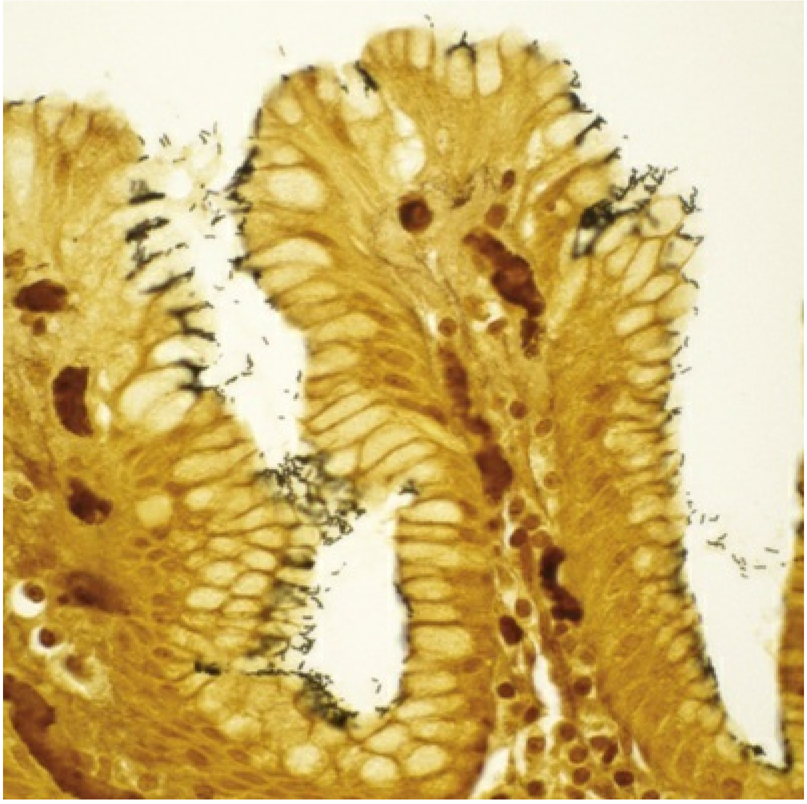

FIGURE 174.4 Gastric mucosa showing high density of *Helicobacter pylori* organisms on its surface (silver stain; original magnification, ×400). (Courtesy of Dr. Milton Finegold, Department of Pathology, Baylor College of Medicine, Texas Children's Hospital.)

The ^{13}C-urea breath test (UBT) using techniques such as a novel laser–associated ratio analysis (LARA)-^{13}C, and the stool antigen tests (particularly new-generation monoclonal tests) have been studied extensively in both adults and children.[10,106,188,191,244–248] Investigations clearly demonstrated utility of these assays in children both for diagnosis and as a test for cure.[244,249,250] Further validation of these assays is required for children younger than 6 years. The polyclonal stool antigen test demonstrated variable performance and had less favorable accuracy compared with the UBT and newer generation monoclonal stool antigen tests.[246,251]

Another method to diagnose *H. pylori* infection in children is detection of specific antibodies in serum, urine, or saliva.[252,253] Detection of serum immunoglobulin G antibodies by enzyme immunoassay (EIA) and Western blot is the most widely used.[254,255]

The sensitivity of most commercially available EIAs, however, is much lower in children than in adults.[256] More recently developed EIAs that use recombinant CagA and VacA antigens require further evaluation in children. As a result, three original pediatric *H. pylori* guidelines, as well as revised Canadian and ESPGHAN-NASGPHAN guidelines for children, recommend against clinical use of serology.[191,257–259]

The “string test” is a novel, relatively noninvasive method (requiring swallowing, 1-hour dwell time, and retrieval) that can provide both isolation of the organism for typing and antimicrobial susceptibility testing.[260–266] In a recent study, strains recovered from strings and biopsy specimens yielded identical or closely related profiles using molecular assays (i.e., randomly amplified polymorphic DNA and PCR for urease B gene) in each of 24 cases tested.[261] Genotypes of *H. pylori* from members of 62 households in Peru were compared using cultures and DNA assays by the string test. The randomly amplified polymorphic DNA fingerprints of 70% of child-mother pairs did not match, nor did the diagnostic gene sequences (>1% DNA sequence difference), independent of the child's age. Most strains from siblings or other paired family members also were unrelated.[264] These data suggest that *H. pylori* infections in the society studied often are community acquired. This small but novel study infers that effective prevention of *H. pylori* infection and associated gastroduodenal disease will require anti −*H. pylori* measures applied community-wide. Although both studies are small in size, they provide evidence that the string test is useful clinically, especially in settings such as in rural communities or areas where pediatric gastroenterologists are not available.

Treatment

Treatment Guidelines

ESPGHAN and NASPGHAN provide clinical practice guidelines recommendations for approach to treatment of *H. pylori* (Box 174.1) and an algorithm for evaluation of a child with suspected infection (Fig. 174.5).[10] The most effective *H. pylori* therapy currently accepted for children is a 2-week, triple therapy regimen that includes a proton pump inhibitor, such as omeprazole or lansoprazole, plus clarithromycin and amoxicillin. Box 174.2 lists accepted, evidence-based eradication therapies for children. *H. pylori* culture and antibiotic sensitivity testing should be made available to monitor population antibiotic resistance and to manage treatment failures. In a follow-up study of 209 children treated with sequential 5-day regimen (fourth in Box 174.2), eradication was achieved in 80% overall but was substantially lower in those with 1- or 2-drug resistance; the authors conclude that sequential therapy cannot be recommended for treatment-naïve children.[267] In studies in adults, quadruple therapy that also includes bismuth subsalicylate or citrate for 7 days has been demonstrated to be highly effective. Quadruple therapy in children, as well as levofloxacin-based therapy, requires additional studies for approval.[268,269] Ranitidine bismuth citrate plus two antibiotics also has been shown to have a high *H. pylori* eradication rate; however, further validation in children is required.[270] In adults, triple therapy including levofloxacin now is recommended as an important component of salvage therapeutic regimens for treatment failures and is being used more widely as part of first-line therapy.[271,272] A meta-analysis showed that rescue therapy with levofloxacin is better tolerated and more effective than quadruple therapy (i.e., proton pump inhibitor plus two antibiotics with a bismuth base).[273]

Box 174.1

Approach to Treatment of *Helicobacter pylori* in Children[a]

1. In the presence of *H. pylori*–positive peptic ulcer disease, eradication of *H. pylori* is recommended.

2. When *H. pylori* infection is detected by biopsy-based methods in the absence of peptic ulcer disease, treatment may be considered.

3. A “test and treat” strategy is not recommended in children.

4. In infected children whose first-degree relative has gastric cancer, treatment may be offered.

5. The duration of triple therapy should be 7 to 14 days. Cost, compliance, and adverse effects should be taken into account.

6. If treatment has failed, 3 options are recommended:

a. EGD with culture and susceptibility testing (including alternative antibiotics), if not performed before

b. FISH on previous paraffin-embedded biopsies if clarithromycin susceptibility testing was not performed previously

c. Modification of therapy by adding an antibiotic, using different antibiotics, adding bismuth, and/or increasing the dose and/or duration of therapy

EGD, esophagogastroduodenoscopy; FISH, fluorescent in situ hybridization; PPI, proton pump inhibitor.

---

PPI-AMO-MET# or PPI-AMO-CLA# or Bismuth-AMO-MET or Sequential therapy
PPI AMO CLA
Noninvasive test for eradictation
HP eradicated?
Yes
No
Observe
Assess + Encourage compliance
CLA resistance or prior CLA therapy?
CLA resistance or prior CLA therapy?
Yes
Unknown
Treat without CLA: PPI-AMO-MET 2 wk or bismuth-based tx
FISH for CLA on paraffin slides of first biopsies
EGD with Culture and CLA testing
Treat according to result of CLA testing
Noninvasive test for eradication
HP eradicated?
Yes
No
Observe
Consider: other antibiotic bismuth quadruple therapy higher dosage

*In areas or populations with a primary clarithromycin resistance rate of >20% or unknown background antibiotic resistance rates, culture and susceptibility testing should be performed, and the treatment should be chosen accordingly.

#If susceptibility testing has not been performed or has failed, antibiotics should be chosen according to the background of the child.

FIGURE 174.5 Algorithm for treatment of *Helicobacter pylori* infection in children. AMO, amoxicillin; CLA, clarithromycin; EGD, esophagogastroduodenoscopy; FISH, fluorescence in situ hybridization; HP, *Helicobacter pylori;* MET, metronidazole; PPI, proton pump inhibitor; PUD, peptic ulcer disease; tx, therapy. (From Koletzko S, Jones NL, Goodman KJ, et al. Evidence-based guidelines from ESPGHAN and NASPGHAN for Helicobacter pylori infection in children. *J Pediatr Gastroenterol Nutr* 2011;53:230–243.)

Box 174.2

First-Line Treatment Recommendations for *Helicobacter pylori* Eradication in Children

- PPI + amoxicillin + metronidazole
- PPI + amoxicillin + clarithromycin
- Bismuth salts (bismuth subsalicylate or subcitrate) + amoxicillin +

metronidazole

- PPI + amoxicillin for 5 days; then PPI + clarithromycin + metronidazole for 5 days

Doses are PPI, 1–2 mg/kg/day; amoxicillin, 50 mg/kg/day; metronidazole, 20 mg/kg/day; clarithromycin, 20 mg/kg/day; bismuth salts, 8 mg/kg/day. Therapy is given in 2 divided doses daily for 10–14 days. Maximal daily doses are amoxicillin, 2 g; metronidazole, 1 g; clarithromycin, 1 g.

See text for additional comment.

PPI, proton pump inhibitor.

Antibiotic Resistance and Follow-Up

Treatment should be guided by knowledge of specific geographic susceptibility patterns because efficacy of eradication is strongly influenced by antibiotic resistance and clinical relapses are invariably associated with failure to eradicate the organism. Emerging resistance makes options for therapy less definitive. In a multinational European study of 1233 patients from northern (3%), western (70%), eastern (9%), and southern Europe (18%), primary resistance rate of *H. pylori* strains obtained from unselected children was high; use of antibiotics for other indications was deemed a major risk factor for primary resistance.[274,275] In this study, overall resistance to clarithromycin was 24%, with higher rates in boys, in children older than 6 years compared with younger than 12 years, and in patients living in southern compared with northern Europe. Overall resistance to metronidazole was 25%, and was higher in children born outside of Europe.

Reports form the US and Europe show resistance rates of 21% to 41% for clarithromycin, 43% to 46% for metronidazole, and up to 5% for amoxicillin.[191,274,275] Metronidazole resistance in developing countries is even greater, up to 80%.[276,277] Follow-up to confirm cure and eradication should be performed using either UBT or *H. pylori* stool antigen test on weeks 4 to 6 after treatment. Reinfection rate appears to be <1% in developed countries but is much higher in developing populations and when more than 1 family member is infected. Monitoring is justified only when the risk for reinfection is increased.

Novel Therapies

Emerging data support the potential role for probiotics in treatment regimens for *H. pylori*. A systematic review with meta-analysis evaluating the addition of *Saccharomyces boulardii* to standard triple therapy significantly increased the rate of *H. pylori* eradication compared with triple therapy alone.[278] One randomized, blinded placebo-controlled trial found that *Lactobacillus casei* also provided higher eradication rates (85% vs. 58%, $P < 0.01$) when added to standard triple therapy.[279] A Cochrane Database review of the role of probiotics in *H. pylori* infection concluded that probiotics do not eradicate *H. pylori* but likely suppress levels in the stomach and, in combination with antibiotics, may increase eradication rates or decrease adverse effects of the multidrug treatment regimens.[280] The use of human lactoferrin as an adjuvant in the treatment of *H. pylori* is a promising novel treatment, but more data are needed to determine its efficacy in the pediatric population.[281,282]

Future Directions

H. pylori has a significant burden of disease in the world's population, especially in developing countries. New molecular assays provide a useful tool for accurate diagnosis; however, the emergence of antibiotic resistance makes treatment and eradication efforts challenging. Several *H. pylori* vaccines have been evaluated in clinical trials.[283–285] One randomized, double-blinded, placebo-controlled, phase 3 trial of an oral recombinant vaccine in >4000 children showed the vaccine was safe and immunogenic with an efficacy of 71%.[286] More studies with long-term follow-up are needed to determine duration of the observed protective effect. These data are promising for a vaccine that could potentially prevent gastric complications of *H. pylori* infection, including peptic ulcer disease and gastric cancer.

Other Gastric and Enterohepatic *Helicobacter* Species

Jonathan D. Crews, Mark A. Gilger

Since the discovery of *Helicobacter pylori* and demonstration of its causal relationship with human gastroduodenal disease, investigators have identified numerous non–*Helicobacter pylori Helicobacter* (NHPH) species. These “other” *Helicobacter* spp., frequently found in domestic and wild animals, also have been recovered from the stomach, intestine, and hepatobiliary system of humans. Although the complete spectrum of human disease syndromes associated with NHPH remains to be fully defined, gastric and enterohepatic diseases have been described.

The Pathogens

There are now >30 formally named species in the genus *Helicobacter*.[1] In addition, there are a number of provisional species that have been named but not yet validated. NHPH are spiral-shaped bacilli that are gram-negative, motile, and microaerophilic. They are broadly grouped as gastric or enterohepatic, based on their biologic niche (Table 175.1).

TABLE 175.1

Gastric and Enterohepatic *Helicobacter* Species Identified in Humans

Species	Location
H. bizzozeronii	Gastric
H. felis	Gastric
H. heilmannii	Gastric
H. pylori	Gastric
H. salomonis	Gastric
H. suis	Gastric
H. bilis	Enterohepatic
H. canadensis	Enterohepatic
H. canis	Enterohepatic
H. cinaedi	Enterohepatic
H. fennelliae	Enterohepatic
H. ganmani	Enterohepatic
H. hepaticus	Enterohepatic
H. pullorum	Enterohepatic

The gastric NHPH spp. are urease- and catalase-positive. They can be distinguished from *H. pylori* by their longer, more tightly coiled morphology and their difficulty to culture in vitro (Fig. 175.1).[2–4] Microscopically, the gastric NHPH spp. are very similar to one another, although differences in size, the presence or absence of periplasmic fibers, and number and distribution of flagella have been described.[4,5] The first gastric NHPH to be discovered was an uncultivated organism, initially called *Gastrospirillum hominis*, and later *Helicobacter heilmannii*.[6,7] Subsequently several additional gastric *Helicobacter* spp. were identified, including *H. felis*, *H. suis*, *H. bizzozeronii*, and *H. salomonis*. The gastric NHPH spp. have been associated with gastritis, peptic ulcer disease, gastric carcinoma, and mucosa-associated lymphoid tissue (MALT) lymphoma in humans.

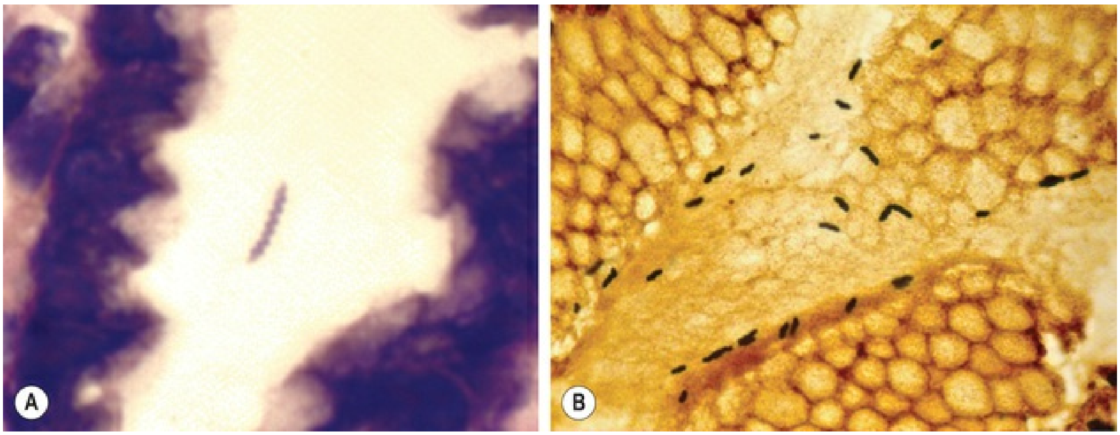

FIGURE 175.1 Morphologic differences between *H. pylori* and *H. heilmannii* s.l. The longer, more tightly-coiled *H. heilmannii* s.l. (A) can be distinguished from *H. pylori* (B) in gastric tissue. *Helicobacter* spp. can be viewed with hematoxylin and eosin stain, Giemsa stain (A), or silver stain (B). (Photo courtesy of Dr. Milton J. Finegold.)

The nomenclature of the gastric NHPH has produced confusion, largely owing to challenges in culturing the various organisms. Historically, long, spiral-shaped, uncultivable organisms in the human stomach were called *H. heilmannii*. However, the sequencing of specific target genes demonstrated that a group of *Helicobacter* spp. was actually present. Haesbrouck and colleagues proposed that *H. heilmannii* sensu lato (*H. heilmannii* s.l.) refer to the whole group of gastric NHPH spp. when only histopathologic or electron microscopic data are available and to reserve the use of species names when definitive identification at the species level is available. The term *H. heilmannii* sensu strictu (*H. heilmannii* s.s.) refers to the particular *H. heilmannii* species.[8] The complete genome for 4 of the 5 gastric NHPH spp. (i.e., *H. suis*, *H. felis*, *H. bizzozeronii*, and *H. heilmannii* s.s.) has been published.[9–12] The genomes reveal that these organisms, while possessing homologues to *H. pylori* genes associated with colonization, lack homologues to important *H. pylori* virulence genes, including the *cag* pathogenicity island and the genes encoding CagA and VacA. An exception is *H. suis*, which contains a VacA homologue.[12] These genetic differences may explain the pathologic differences that have been observed between the gastric NHPH and *H. pylori*.

The enterohepatic *Helicobacter* spp. are fastidious organisms found in the intestines, liver, and biliary tract of humans, other mammals, and birds. They have ultrastructural and physiologic features in common with gastric *Helicobacter* spp.; however, they generally do not colonize the gastric mucosa. Several enterohepatic NHPH spp. have been found in humans, including *H. bilis*, *H. canis*, *H. cinaedi*, *H. fennelliae*, *H. pullorum*, and *H. hepaticus* (see Table 175.1).[5] The enterohepatic NHPH spp. have been associated with gastroenteritis, hepatitis, benign biliary disease, and hepatobiliary malignancies. *H. cinaedi* has been reported to cause bacteremia, cellulitis, and arthritis.[13] Recent interest in the enterohepatic NHPH has resulted in sequencing of the entire genome for several species, including *H. cinaedi*, *H. bilis*, *H. canis*, *H. hepaticus*, and *H. pullorum*.[14–16]

Epidemiology

The other gastric and enterohepatic *Helicobacter* spp. are found in a wide variety of animals.[17] Early observations of NHPH infections were made in cats and dogs[18–20]; subsequently, organisms have been identified in other domestic animals, including cattle, pigs, chickens, sheep, ferrets, mice, rats, and hamsters.[5,21,22] Many wild animals are also colonized by NHPH, including monkeys, cheetahs, mountain lions, ocelots, and birds.[23–25] Marine animals, including dolphins and whales, have been reported to have gastric ulcerations associated with NHPH.[26–29] Although there appears to be a large degree of host specificity among the NHPH, interspecies transmission has been observed.[17,30] Notable *Helicobacter* spp. and their associated hosts include *H. felis*, *H. bizzozeronii,* and *H. heilmannii* in cats and dogs[18,19,31]; *H. suis* in pigs[4,32]; *H. bilis* and *H. hepaticus* in rodents[16,33]; *H. cinaedi* in gerbils and hamsters[34,35]; and *H. pullorum* in chickens and birds.[36] *H. cinaedi* seems to have the broadest host range of the *Helicobacter* spp.[17]

Because the NHPH spp. are common in animals, it has been postulated that infection in humans may represent zoonotic transmission. This position is supported by the finding of similar organisms in humans and their pet dogs or cats and by the frequency of animal contact among infected individuals.[37–43] The results of a questionnaire given to 662 patients with either *H. heilmannii* s.l. or *H. pylori* infection found that contact with dogs, cats, and pigs was strongly associated with *H. heilmannii* s.l. infection.[42] In a notable case, a 12-year-old girl developed gastritis and *H. heilmannii* s.l. infection after moving to a farm. After successful treatment of the infection, her symptoms returned. Endoscopy was performed on her pet dog, which had a long history of vomiting, revealing a morphologically identical *H. heilmannii* s.l. organism. The symptoms of both the child and the dog were eradicated after retreatment of the child with concurrent treatment of the dog.[39] Given the recent advances in genetic technologies, the dynamics of *Helicobacter* transmission is sure to become more evident in the near future.

The prevalence of *H. heilmannii* s.l. in adults and children undergoing upper gastrointestinal tract endoscopy is <0.5% to 2%.[44–48] Reports of children with gastritis or gastric ulcers associated with *H. heilmannii* s.l. infection have been published from most parts of the world, including Western and Eastern Europe, South America, North America, Japan, and other parts of Asia.[3,44–48] In one of the larger clinical-pathologic correlation studies, 6077 gastric mucosal biopsies (2 antrum and 1 corpus samples per patient) were systematically analyzed from patients with duodenal ulcers (n = 946) or nonsteroidal anti-inflammatory drug (NSAID)-associated gastric ulcers (n = 281 patients). *H. heilmannii* s.l. was detected in 6 (0.5%) of 1227 patients (0.2% of 7871 biopsies). Of these, 4 were patients with duodenal ulcers (4/946; 0.4%) and 2 were patients with NSAID-associated gastric ulcers (2/281; 0.7%).[45] Recently investigators have employed molecular methods, typically polymerase chain reaction (PCR) assays, to distinguish among the *H. heilmannii* s.l. species in human gastric mucosa. These studies have found that *H. suis* is the most common gastric NHPH and that 5% to 15% of individuals with gastric NHPH are infected with more than one species.[19,49–51]

The overall prevalence of the enterohepatic NHPH spp. in humans is unclear. Several enterohepatic NHPH spp., including *H. canadensis*, *H. canis*, *H. pullorum*, and *H. bilis*, have been isolated from the intestines of children and adults with gastroenteritis.[36,52–54] Additionally, enterohepatic NHPH spp. have been detected in liver, bile, and gallbladder tissue.[55,56] Although they have been associated with gastroenteritis, hepatitis, and hepatobiliary malignancies in humans, whether the enterohepatic NHPH spp. contribute to human intestinal and hepatobiliary disease has not been confirmed. An exception is found with *H. cinaedi* and *H. fennelliae,* which have been cultured from homosexual men with human immunodeficiency virus (HIV) infection and proctitis or proctocolitis.[57] Additionally, *H. cinaedi* is increasingly identified as a cause of bacteremia in immunocompromised hosts,[13] particularly in Japan, where it has been found in up to 0.2% of total positive blood culture samples.[58–60]

A role for *Helicobacter* spp. in inflammatory bowel disease (IBD) has been proposed; however, studies are conflicting.[61–65] For example, among 179 children undergoing colonoscopy, members of the Helicobacteraceae family were detected by PCR in 32 (42%) of 77 children with Crohn disease compared with 23 (23%) of 102 controls ($P < 0.01$). When stratified by *H. pylori* or non-*pylori Helicobacter*, infection with NHPH was significantly more prevalent in patients with Crohn disease than in controls ($P = 0.04$).[65] Alternatively, 44 children with treatment-naïve, de novo IBD had a similar prevalence of *Helicobacter* spp. as 42 children with normal colons (11% vs. 12%; $P = 1.00$).[63] Further research is needed to determine whether *Helicobacter* spp. contribute to the pathogenesis of IBD.

Clinical Manifestations

H. heilmannii s.l. has been reported in cases of gastritis, peptic ulcer disease, gastric carcinoma, and MALT lymphoma. Acute or chronic gastritis is the most frequent histopathologic finding among individuals with *H. heilmannii* s.l. infection.[44,66] Gastric and duodenal ulcers also have been described, although they appear to be less frequent.[44,66] In a prospective study among 580 children with dyspepsia who underwent upper gastrointestinal tract endoscopy, 5 (0.9%) children had *H. heilmannii*–like organisms. In addition, 4 of the 5 had mild to moderate gastritis noted in the antrum, and 1 child had a gastric ulcer.[44]

Investigators have noted differences in gastritis associated with *H. heilmannii* s.l. and that seen with *H. pylori*.[45,67,68] Stolte and colleagues compared 202 patients with gastritis associated with *H. heilmannii* s.l. and 202 matched control patients with *H. pylori* –associated gastritis. They found that most of the gastritis from *H. heilmannii* s.l. was focal and localized to the antrum. Additionally, *H. heilmannii*–associated gastritis had less severe neutrophilic and lymphocytic infiltration compared with those with *H. pylori*.[67]

H. heilmannii s.l. infection has been associated with MALT lymphomas and less commonly with gastric carcinoma.[46,67–71] In a retrospective study from Japan of 4074 patients undergoing esophagogastroduodenoscopy, 15 patients were found to have *H. heilmannii* s.l. infection: 11 had chronic gastritis, and 4 had MALT lymphoma.[46] Eradication of *H. heilmannii* s.l. infection resulted in remission of MALT lymphoma in this study and others.[46,68,69] MALT lymphomas have been observed in animals experimentally infected with *H. felis*, *H. heilmannii* s.s., and *H. suis*.[72,73] In a murine study (BALB/c mice), MALT lymphomas were detected in up to 25% of animals infected with *H. heilmannii* s.l., and the prevalence of lymphoma was dependent on the duration of infection.[72]

The causal relationship between infection with *H. heilmannii* s.l. and gastric disease in humans is supported by animal models, which demonstrate the capacity of the organisms to cause disease and the observation that eradication of the organism in humans is associated with a relief of symptoms and resolution of pathology.

Several enterohepatic NHPH spp. have been isolated from humans with acute and chronic diarrhea.[36,52–54] *H. canis* was isolated from the stool of a 5-year-old child with gastroenteritis.[54] Additionally, *H. bilis* and *H. pullorum* have been identified in humans with self-limited diarrheal illnesses.[36,53,74] Additional research, however, is needed to implicate these organisms in the pathogenesis of gastroenteritis.

H. cinaedi and *H. fennelliae* were originally described in 1984 in homosexual men with HIV infection who had proctitis or proctocolitis.[57] Since then, invasive disease from these organisms has been described predominantly in immunocompromised patients, with only rare reports of infection in immunocompetent hosts.[59,75,76] *H. cinaedi* is increasingly recognized to cause bacteremia. Fever is present in most patients with *H. cinaedi* bacteremia, with some patients experiencing a macular rash, abdominal pain, or diarrhea. An accompanying cellulitis, which can be multifocal, has been described.[13,77] *H. cinaedi* has also been reported to cause septic arthritis, endocarditis, and meningitis.[78,79] A case of neonatal sepsis and meningitis has been described.[80] Nosocomial acquisition of *H. cinaedi* bacteremia in immunocompromised patients can occur.[81]

H. hepaticus, *H. bilis*, and *H. pullorum* are capable of producing hepatobiliary disease in animals. They have been associated with hepatitis, cholecystitis, cholelithiasis, hepatocellular carcinoma, and cholangiocarcinoma in various animal models.[33,82–84] Their role, if any, in the pathogenesis of human hepatobiliary disease, however, has not been fully explained.

Enterohepatic NHPH can be detected in the hepatic tissue of adults and children with chronic liver disease. Casswall and colleagues analyzed pediatric liver samples with a *Helicobacter*-specific PCR assay and found that 3 (13%) of 23 liver samples from children with primary sclerosing cholangitis and ulcerative colitis had evidence of *Helicobacter* infection; additionally, 1 of 2 children with autoimmune hepatitis were infected.[55] Another pediatric study found *Helicobacter* spp. in 40 (66%) of 61 liver biopsies of patients with various liver disorders and in 4 (40%) of 10 liver biopsies from control subjects without liver disease. On molecular analysis of the 16S rDNA sequences, there was 99% to 100% similarity to *Helicobacter* spp. previously reported to colonize liver tissue, including *H. canis*, *H. bilis*, and *H. ganmani*, a recently described anaerobic *Helicobacter* species.[85,86] Additionally, a study found a greater prevalence of antibodies to enterohepatic NHPH in patients with autoimmune liver disease than in healthy blood donors.[87] Further studies are needed to determine whether there is a causal link between *Helicobacter* spp. and liver diseases in adults and children.

Helicobacter spp. have been identified in bile and gallbladder tissue in adults and children with hepatobiliary disease.[56,88] An early study among 46 Chileans with chronic cholecystitis undergoing cholecystectomy was unable to cultivate *Helicobacter* spp. from bile or gallbladder tissue; however, 13 (56%) of 23 bile samples and 9 (39%) of 23 gallbladder tissue were positive by PCR for *Helicobacter* spp. Subsequent 16S rRNA cloning and sequencing identified strains of *H. bilis* and *H. pullorum*.[56] The role of *Helicobacter* spp. in cholelithiasis has also been investigated. A meta-analysis of 18 case-control studies between 1998 and 2011 was performed to determine the association between *Helicobacter* spp. and biliary lithiasis. Although they found significant heterogeneity among the studies, a higher pooled infection rate was observed in the lithiasis group for *H. pylori* (36% vs. 27%, P = 0.01) and *H. hepaticus* (31% vs. 21%, P = 0.02).[88]

Research is ongoing to determine whether NHPH spp. contribute to the pathogenesis of hepatobiliary malignancies, similar to the carcinogenic role of *H. pylori* in stomach cancer.[84,89] Mice experimentally infected with *H. hepaticus* develop chronic hepatitis and liver tumors.[33,82] In one study of adult patients with hepatocellular carcinoma, liver samples from 3 (11%) of 28 patients were infected with NHPH.[90] Another study of liver samples from patients with primary liver carcinoma found *Helicobacter* spp. 16S rDNA in 8 (40%) of 20 samples, whereas none of the controls was positive.[91] More recently, Segura-López and colleagues found a higher *H. bilis* infection rate among individuals with extrahepatic cholangiocarcinoma (44 of 103 cases) than with benign biliary disease (19 of 91 controls). When analyzed by cancer site, *H. bilis* was strongly associated with cancer in the common bile duct.[92]

Whether enterohepatic NHPH contributes to the pathogenesis of human hepatobiliary disease is unclear. Nonetheless, as investigators continue to expand the use of advanced genetic technologies, the role of enterohepatic NHPH in human health is certain to become more apparent.

Diagnosis

Most gastric and enterohepatic NHPH spp. are identified by histopathologic detection or through molecular techniques because in vitro isolation is difficult.[93,94] Growth of NHPH is complex and requires special conditions, including a microaerobic environment; many strains grow better in an atmosphere of 5% to 10% hydrogen. The *Helicobacter* spp. grow slowly and can be overgrown easily by contaminating gastric or enteric flora. Enterohepatic *Helicobacter* are usually identified from stool through the use of methods for isolating *Campylobacter* spp. However, they can be susceptible to common antimicrobial agents added to commercial *Campylobacter* media.

The gastric NHPH spp. are typically diagnosed by histopathology based on the organism's morphology or by molecular testing. The longer, more tightly coiled *H. heilmannii* s.l. can be distinguished from *H. pylori* in gastric tissue on light microscopy with hematoxylin and eosin, Giemsa, or Warthin-Starry stain. Very few laboratories have been able to culture the gastric

NHPH; only *H. bizzozeronii* and *H. felis* have successfully been grown from human gastric mucosa.[95–97] For species identification, 16S and 23S rRNA sequencing permits distinction between *H. suis* and *H. heilmannii* s.l. species.[3,32] Multiplex PCR assays targeting urease A and B genes (*ureA*, *ureB*), are used by research laboratories for further species identification.[93,94] This level of identification is rarely clinically necessary.

The urea breath test and rapid urease test have limited use in the diagnosis of gastric NHPH in humans because of their low sensitivity, although they appear to perform well in domestic animals. Additionally, testing for *H. pylori* antibodies and *H. pylori* stool antigen has not been found to be useful in identifying NHPH spp.[98]

H. cinaedi can be recovered by automated blood culture systems, usually from the aerobic bottle. Most isolates are detected after ≥5 days of incubation.[13,58] The organism can be difficult to observe with Gram staining, and thus acridine orange staining, darkfield microscopy, or Giemsa staining may be required. Because of morphology and biochemical properties that are similar to enteric *Campylobacter* spp., definitive identification often requires PCR. Rapid identification of *H. cinaedi* from blood culture samples may be possible in the future with matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry.[99]

Treatment

Treatment for *H. heilmannii* s.l. infection is indicated when gastric pathologic changes are severe and are associated with gastrointestinal symptoms. The same guidelines for when to initiate *H. pylori* eradication should be followed for *H. heilmannii* s.l. infection. Likewise, the treatment regimen for *H. heilmannii* s.l. infection is identical to the triple-therapy regimen for *H. pylori*—a proton pump inhibitor and clarithromycin with amoxicillin or metronidazole.[3] Antimicrobial susceptibility testing of gastric NHPH spp. has found them to be highly susceptible to ampicillin, clarithromycin, and tetracycline, although *H. felis* strains with an elevated minimal inhibitory concentration (MIC) for metronidazole have been reported.[100]

When an NHPH is identified from a nonsterile site, the significance of the patient's illness and the likelihood that it could be explained by the identified organism should be considered before embarking on treatment. Generally, treatment is warranted when NHPH is identified from a sterile site.

Bacteremia from *H. cinaedi* has been successfully treated with 14 days of third-generation cephalosporins or tetracyclines.[77] Alternatively, several authors prefer prolonged treatment for 2 to 6 weeks given the risk for recurrence.[13,59,101] Susceptibility breakpoints have not been defined for *H. cinaedi*. Nonetheless, the MICs of imipenem, minocycline, and gentamicin are generally low for *H. cinaedi*, whereas elevated MICs to ciprofloxacin and clarithromycin have been observed. Isolates with mutations conferring resistance to ciprofloxacin and clarithromycin have been described.[102]

Key Points

Gastric and Enterohepatic *Helicobacter*

- Gastric and enterohepatic *Helicobacter* are widespread among animals and have infrequently been associated with infections of the stomach, intestine, and hepatobiliary system of adults and children.
- *Helicobacter heilmannii* sensu lato organisms are distinguished from *Helicobacter pylori* on gastric tissue based on their longer, more tightly coiled morphology.
- *Helicobacter cinaedi* bacteremia occurs in immunocompromised patients and can be associated with multifocal cellulitis and arthritis.
- Detection of *H. cinaedi* in blood cultures requires prolonged incubation.
- Research is ongoing to determine the contribution, if any, of enterohepatic *Helicobacter* to adult and pediatric diseases of the intestines and hepatobiliary system.

Kingella Species

Pablo Yagupsky

The genus *Kingella* comprises four species, of which *Kingella potus* has been isolated from a wound caused an animal bite in an adult patient,[1] and three other species that have been implicated in pediatric infections: *Kingella denitrificans,* which is an opportunistic and a rare cause of endocarditis[2] and child vaginitis[3]; *Kingella oralis,* which is associated with periodontitis[4]; and *Kingella kingae,* which is a common pathogen of young children and will be discussed in detail in this chapter.

Microbiology

Kingella kingae is a facultative anaerobic ß-hemolytic bacterium that appears as short chains of plump bacilli with tapered ends (Fig. 176.1).[5] *Kingella kingae* grows on blood agar and chocolate agar plates, producing marked impressions on the medium's surface. It fails to grow on MacConkey or Krigler agar, and its growth is enhanced in a CO_2-enriched atmosphere.[5] The organism is nonmotile, exhibits positive oxidase activity, produces acid from glucose and maltose but not from other sugars, and can be identified readily by commercial systems such as API NH and VITEK 2 (bioMérieux, Marcy-l'Etoile, France),[6] matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometry technology,[7] and 16S rDNA gene sequencing.[8]

RBC, red blood cell.

Virulence and Pathogenesis

The pathogenesis of invasive *K. kingae* disease is believed to begin with colonization of the tonsillar crypts,[9] and organisms recovered from the blood of children with invasive infections are genotypically identical to those isolated from the oropharynx.[10] Colonization involves adherence to epithelial cells, which is mediated by type IV pili that share homology with the major pilin of other gram-negative pathogens.[11–13] Children with *K. kingae* disease frequently have had symptoms consistent with a viral upper respiratory tract infection, herpetic gingivostomatitis, hand-foot-and-mouth disease, or herpangina, suggesting that breach of the mucosal lining facilitates bloodstream invasion.[5,14–18] In addition, the organism produces a potent extracellular toxin that belongs to the RTX family, capable of lysing epithelial and synovial cells, leukocytes, and macrophages.[19] This toxin may disrupt the respiratory epithelium and contribute to pathogenesis by damaging skeletal tissues.[19] *K. kingae* strains exhibit remarkable variation in their invasive capacities. Whereas some strains frequently are carried without symptoms and seldom if ever are isolated from patients with clinical disease, other strains cause a substantial proportion of the disease burden, including bacteremia, skeletal system infections, and endocarditis.[5] Preliminary studies suggest that *K. kingae* elaborates a polysaccharide capsule to promote survival in the bloodstream, explaining the tendency of the organism to infect young children who have not yet developed a mature T-lymphocyte–independent immune response.[5,20]

Immunity

In a longitudinal study, serum titers of immunoglobulin G (IgG) antibodies against *K. kingae* outer membrane proteins were high at 2 months of age, reached a nadir at the age of 6–7 months, remained low until the age of 18 months, and increased at 24 months, whereas serum IgA levels were lowest at 2 months and peaked in the second year.[21] These findings and the low attack rate of disease and absence of pharyngeal carriage in early infancy suggest that immunity to colonization and disease is conferred by maternal antibodies. The high pharyngeal prevalence of *K. kingae* and the increased incidence of invasive disease among children 6 to 24 months old coincide with the age at which antibody levels are lowest. Increasing antibody levels in older children presumably reflect immunologic maturation and cumulative experience with *K. kingae* or with cross-reacting antigens, resulting in an efficient reduction of carriage and burden of disease.[21] Asymptomatic pharyngeal colonization probably is the immunizing event. Exposed epitopes, however, are polymorphic, and the immune response appears to be incomplete and strain specific and does not prevent colonization by an antigenically dissimilar strain.[22]

Epidemiology

Carriage

K. kingae is carried asymptomatically on the tonsils and is almost never isolated from nasopharyngeal cultures.[23,24] Children usually acquire *K. kingae* after the age of 6 months, and colonization is characterized by frequent turnover of strains.[25,26] The colonization rate increases to 9% to 12% at the ages of 12 through 24 months and declines thereafter, paralleling the age-related incidence of invasive disease (Fig. 176.2).[26] *K. kingae* spreads from child to child by close contact between siblings and playmates, and childcare center attendance increases the risks for colonization and transmission.[23,25] A carriage rate of 28% has been found among children in childcare,[23] and clusters of invasive infections have been detected in childcare facilities in the United States,[27,28] France,[16,29] and Israel.[30,31] In a study of 3 clusters of invasive infection in closed communities, 54% of asymptomatic preschool-aged children carried the *K. kingae* outbreak strain, indicating high transmissibility and successful colonization.[31]

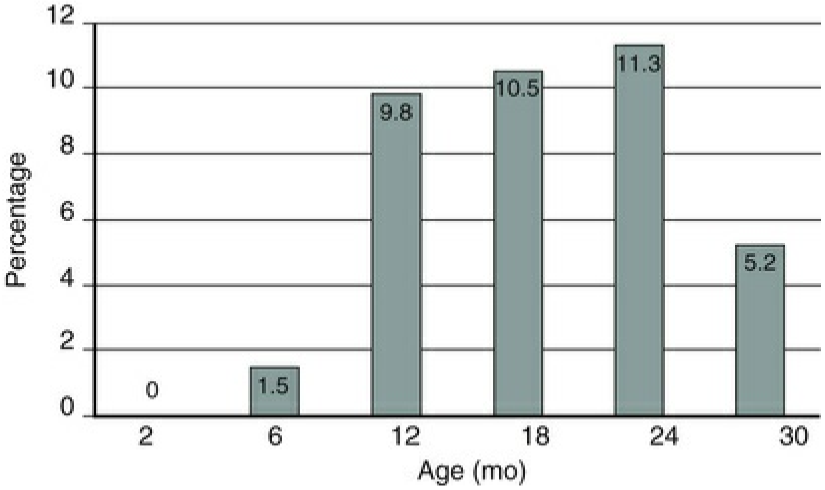

FIGURE 176.2 Point prevalence of pharyngeal carriage of *Kingella kingae* in a cohort of 716 children sampled sequentially between the ages of 2 and 30 months.

Invasive Infections

K. kingae infections are almost limited to young children. Of 147 infected patients over a 27-year period in southern Israel, only 1 was an adult; 145 of the 146 children were younger than 4 years, yielding an annual incidence of invasive disease of 9.4/100,000 in this age group.[32] Infection is rare in the first 6 months of age, paralleling lack of *K. kingae* colonization in early childhood (Fig. 176.3).[26,32]

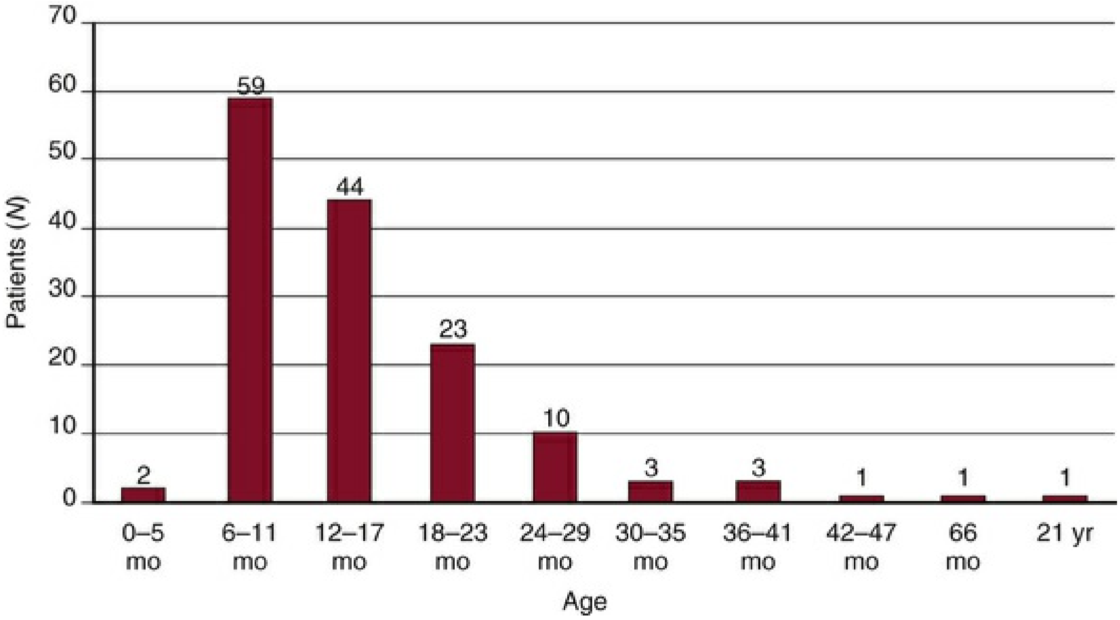

FIGURE 176.3 Age distribution of 147 Israeli patients with culture-proven *Kingella kingae* infections.

Most infected children younger 4 years are otherwise healthy, whereas older children and adults often have immunosuppressing conditions, malignancy, or cardiac valve pathology.[5,18,32,33] In a multicenter Israeli study, none of 291 previously healthy children with an invasive *K. kingae* infection were older than 48 months, whereas 9 of 22 (41%) children with underlying diseases were older than 48 months.[32] The disease is more common among males, with a male-to-female ratio of 1.3.[32]

Invasive *K. kingae* infections occur throughout the year and are most common during November and December and least common between February and April.[5,18,32–34]

Clinical Manifestations

Children with *K. kingae* infections other than endocarditis usually are only mildly or moderately ill,[5,18,32,35–40] and generally, a single focus of infection is detected.[41] Most children have moderate fever, but 23% are afebrile, and acute phase reactants frequently are normal or only slightly elevated.[5,32] In a series of children with culture-proven *K. kingae* disease, 172 of 301 (57%) had a white blood cell (WBC) count of <15,000/mm^3, and 18 of 82 (22%) had normal C-reactive protein values.[32] In the 321 children with invasive *K. kingae* infection enrolled in a nationwide collaborative study in Israel, involvement of the skeletal system was observed in 169 (53%), bacteremia with no focus in 140 (44%), endocarditis in 8 (2%), and pneumonia in 1 (1%) case.[32]

Osteoarticular Infections

Pyogenic Arthritis.

Pyogenic arthritis is the single most common presentation of *K. kingae* infection and usually affects the knee, ankle, or hip.[5,32] Less frequently, *K. kingae* invades the wrist, shoulder, elbow, and small articulations such as metacarpophalangeal, sternoclavicular, and tarsal joints, which are rarely infected by other bacteria.[5,32,42,43]

Lack of leukocytosis has been observed in 76 of 149 (51%) children with *K. kingae* arthritis, and 18 of 8 (23%) had <50,000 WBC/mm^3 in synovial fluid.[32] Gram stain of synovial fluid usually is negative, probably owing to low bacterial density.[5,32,38,44–46] Because of mild symptoms and benign laboratory findings, diagnosis of *K. kingae* arthritis requires a high index of suspicion, and the disease can be misdiagnosed as transient synovitis. Children younger than 3 years presenting with an “irritable hip” should be carefully evaluated to exclude *K. kingae* arthritis, including performance of blood culture and joint tap, and the aspirated synovial fluid should be inoculated in blood culture vials and submitted for nucleic acid amplification testing.[47]

Osteomyelitis.

K. kingae osteomyelitis especially affects the long bones, although involvement of the calcaneus, talus, sternum, clavicle, or patella also can occur.[5,38,42] Primary involvement of the epiphysis or apophysis of the long bones, which is only exceptionally observed in osteomyelitis caused by traditional pathogens, is frequently documented in *K. kingae* infections.[48,49] Patients with *K. kingae* osteomyelitis have a significantly more prolonged duration of symptoms before admission compared with children with other bacterial arthritides (9.2 ± 9.4 days vs. 3.2 ± 3 days, respectively) and have a lower body temperature (37.7° ± 1°C vs. 38.4° ± 0.9°C, respectively).[32] Despite the diagnostic delay of *K. kingae* osteomyelitis, chronicity and orthopedic sequelae are the exception.[5,50]

Spondylodiskitis.

K. kingae is the most common etiology of hematogenous spondylodiskitis in children 6–48 months of age.[32,51–53] Bloodstream organisms appear to reach the intervertebral disks through a network of vessels that enters the annulus from the cartilaginous vertebral end plates and is obliterated in older children.[52] *K. kingae* spondylodiskitis generally involves the lumbar discs, followed by the thoracolumbar, lumbosacral and cervical intervertebral spaces. Diskitis manifests with limping, lumbar pain, back stiffness and loss of the normal lordotic curvature on examination, refusal to sit or walk, neurologic symptoms, or abdominal complaints. Plain radiograph or magnetic resonance imaging demonstrates narrowing of the intervertebral space.[5] Because blood cultures are negative in most patients and obtaining a tissue specimen for culture is difficult, nucleic acid amplification tests on blood play an important role in establishing the etiology.[53,54] Children with *K. kingae* spondylodiskitis respond well to antibiotic therapy and recover without sequelae.[5]

Abortive Skeletal System Infections.

Although bone and joint infections are not considered self-limited diseases, transient involvement of the skeletal system during *K. kingae* bacteremia is reported.[55–57] Children may limp or refuse to walk or bear weight but have objective signs of osteoarthritis and may have a normal blood WBC and imaging study; fever and symptoms have resolved when blood cultures become positive. It seems prudent to administer antimicrobial therapy to all patients from whom *K. kingae* is isolated from a normally sterile site.

Other Infections

Soft Tissue Infections.

Soft tissue infections, including cellulitis,[58] tenosynovitis or dactilytis,[18,59] bursitis,[60] subcutaneous,[61] presternal,[42,62] and intramuscular[63] abscesses have been reported.

Bloodstream Infections.

Bloodstream infection (BSI) without focus is the second most frequent presentation of pediatric *K. kingae* infections.[14,18,32,33] In a large study, only one half of children with this condition had a body temperature of ≥39°C, and one third had a WBC count of <15,000 cells/mm^3. Algorithms that rely on body temperature and WBC count to pursue BSI are not sensitive to detect *K. kingae*.[32,64] A maculopapular rash, resembling disseminated neisserial infection, has been described in a few patients.[44,65–67]

Endocarditis.

K. kingae is included in the so-called HACEK group of organisms that is collectively responsible for up to 5% of cases of bacterial endocarditis. In contrast to other *K. kingae* infections, endocarditis also has occurred in older children and adults.[5] In approximately one half of patients, the infection affects a native valve. Predisposing cardiac malformation or rheumatic disease is observed commonly, but many pediatric patients have previously normal valves.[5,28,68–72] Typically the left side of the heart is involved, usually the mitral valve. Despite the remarkable susceptibility of the bacterium to antibiotics and the benign clinical picture observed in other invasive *K. kingae* infections, the course of endocarditis is severe and frequently is characterized by life-threatening complications such as cardiac failure, septic shock, mycotic aneurysms, pulmonary infarctions, meningitis, and cerebrovascular septic emboli. Case-fatality rate exceeds 10%.[28,68–72] Because of the potential severity of endocarditis, routine echocardiographic evaluation of all individuals from whom *K. kingae* is isolated from a normally sterile site has been recommended.[73]

Lower Respiratory Tract Infections.

K. kingae has been isolated from the blood or respiratory secretions of previously healthy and immunocompromised adult and pediatric patients with epiglottitis, laryngotracheobronchitis, pneumonia, or pyothorax, suggesting that the organism can cause middle and lower respiratory tract infections.[5,32]

Meningitis.

K. kingae meningitis can occur as a primary infection[74–78] or as a complication of endocarditis.[41,79,80] The age distribution is noticeable in that one-half of cases have occurred in adolescents and young adults.[5]

Ocular Infections.

K. kingae has been isolated from patients with a variety of ocular infections such as orbital and periorbital cellulitis,[5,81] eyelid abscess,[82] endophthalmitis,[44,83] and corneal ulcer.[84]

Diagnosis

Attempts to isolate *K. kingae* on routine solid media frequently are unsuccessful, and recovery can be improved substantially by inoculating synovial fluid aspirates and bone exudates into blood culture vials of the BACTEC (Becton Dickinson, Cockeysville, MD),[85] BacT/Alert (Organon Teknika Corporation, Durham, NC),[86,87] Hémoline DUO (bioMérieux, Paris, France),[88] and Isolator 1.5 Microbial Tube (Wampole Laboratories, Cranbury, NJ)[46] systems, suggesting that pus exerts an inhibitory effect and dilution enables bacterial growth.[85] In two studies in which joint fluid aspirates from young children with arthritis was inoculated into broth blood culture vials, *K. kingae* was isolated in one half of culture-proven bacterial arthritis.[37,89]

Detection of *K. kingae* by nucleic acid amplification techniques is a remarkable aid to diagnosis and is rapid.[90] Using homemade nucleic acid amplification assays targeting the RTX toxin or *cpn60* encoding genes, enhanced detection of *K. kingae* in bone and joint specimens by fourfold compared with routine and blood culture vial cultures, and demonstrated that the organism is responsible for a large fraction of culture-negative cases of pyogenic arthritis and osteomyelitis and is the leading etiology of skeletal system infections in children 6–48 months of age.[5,38–40,91,92]

Treatment

K. kingae is almost always susceptible to penicillins, cephalosporins, aminoglycosides, macrolides, trimethoprim-sulfamethoxazole, and fluoroquinolones.[5] β-Lactamase production is limited to a few clones, and its prevalence shows wide geographic variability, being rare among invasive isolates in continental Europe and Israel but common in Minnesota and Iceland.[93–98] The trait, encoded in the chromosome or in a plasmid, confers low-level resistance to penicillin and ampicillin, but the organism remains susceptible to cephalosporins.[99] As a measure of caution, all *K. kingae* isolates from normally sterile sites should be tested routinely for β-lactamase production.[96] The organism exhibits decreased susceptibility to oxacillin and is fully resistant to trimethoprim and glycopeptide antibiotics.[18,94,100] Nearly 40% of isolates are resistant to clindamycin.[100]

Because of the lack of specific guidelines for the treatment of *K. kingae* infections, patients have been administered a variety of antibiotics, drug combinations, and courses of therapy typical of infections caused by more traditional pathogens.

Bone and Joint Infections.

Empiric drug therapy for skeletal infections usually consists of intravenous administration of a second- or third-generation cephalosporin, pending culture results. When vancomycin and clindamycin are used instead for empiric treatment for skeletal system infections, a β-lactamase–inhibiting agent should be added in children younger than 4 years.[5,101]

When *K. kingae* is detected, therapy frequently is changed to parenteral ampicillin (after β-lactamase production is excluded), cefuroxime, or a third-generation cephalosporin. Parenteral administration of a first-generation cephalosporin such as cefazolin, followed by oral cephalexin, also is suitable. Normalization of body temperature, improvement of local signs, decreasing erythrocyte sedimentation rate, and C-reactive protein levels are used to guide a change to oral antibiotics and to determine the duration of therapy.[5,102–104] Treatment has varied from 2 weeks to 3 months for *K. kingae* arthritis,[18] from 3 weeks to 6 months for osteomyelitis,[18] and from 3 to 12 weeks for spondylodiskitis.[51,52]

Bloodstream Infection.

Children with *K. kingae* BSI and no focal infection generally are treated with an intravenous cephalosporin and subsequently are given an oral β-lactam agent. Patients respond favorably to a 1- to 2-week antibiotic course.[14,18]

Endocarditis.

Patients with *K. kingae* endocarditis usually are treated with an intravenous β-lactam drug alone or in combination with an aminoglycoside for 4 to 7 weeks. Careful assessment and early surgical intervention are necessary for life-threatening complications unresponsive to medical therapy.[5,72]

Key Points

Diagnosis and Management of *Kingella kingae* Infection

Microbiology

- Gram-negative encapsulated coccobacillus in pairs or short chains
- Strains differ in their invasive capabilities.
- β-Lactamase production (variable prevalence) causes penicillin and ampicillin resistance.

Epidemiology

- Normal oropharyngeal flora
- Highest prevalence (10%) at 1–2 years of age, especially among attendees of childcare centers
- Clustering of infection in childcare settings supports person-to-person transmission.
- Antecedent upper respiratory tract infection or stomatitis suggests that disruption of mucosal barrier facilitates invasion.
- Causes bacteremic infections with predilection for osteoarticular or cardiac focus
- Mildly abnormal (or normal) temperature and acute phase reactants are common.

- Endocarditis has severe complications and high mortality rate

Diagnosis

- Inoculation of skeletal system exudates onto solid media is suboptimal.

- Recovery from osteoarticular specimens is enhanced by inoculation of Bactec or BacT/Alert automated blood culture systems.

- Polymerase chain reaction assay improves detection of *K. kingae* from blood and osteoarticular specimens.

Treatment

- Isolates from normally sterile sites should be tested for β-lactamase production.

- Penicillin is drug of choice for β-lactamase–negative infections.

- Susceptible generally to cephalosporins, amoxicillin-clavulanate, and ciprofloxacin

- Resistant to vancomycin and clindamycin

- Addition of gentamicin may be beneficial for treating endocarditis.

Duration of Therapy

- Response to therapy usually is rapid, and early transition from parenteral to oral therapy is possible (see text).

- Recovery without sequelae is expected for osteoarticular infections.

- Patients with endocarditis require intravenous therapy, may require early surgery for life-threatening complications, and can have chronic sequelae.

Legionella Species

Lorry G. Rubin

Investigation of an outbreak of pneumonia among attendees at an American Legion Convention in Philadelphia in 1976 revealed a previously unrecognized causative pathogen, *Legionella pneumophila.*[1,2] Infection with *Legionella* spp. occurs in sporadic and outbreak forms and is one etiology of both community-acquired and nososcomial pneumonia and is called *legionnaires' disease*, or *legionellosis*. *Legionella* spp. also is associated with Pontiac fever, a rare illness that occurs in outbreak form consisting of a short-incubation, self-limited influenza-like illness primarily affecting adults and causing symptoms of fever, malaise, myalgia, chills, and headache.[3,4]

The genus *Legionella* in the family Legionellaceae currently consists of at least 55 species and at least 70 serogroups.[5–7] *L. pneumophila* serogroup 1 is responsible for 50% to 90% of human infections.[6–8] Other *L. pneumophila* serogroups, especially serogroup 6 and *L. bozemanii, L. micdadei,* and *L. longbeachae,* cause most of the remainder of human infections.[7,8] Patients with infections caused by *Legionella* spp. other than *L. pneumophila* are more likely to be immunocompromised.[7] *Legionella* are nutritionally fastidious, motile, non–spore-forming aerobic bacilli. In tissue, *Legionella* organisms appear as short bacilli or coccobacilli with nonparallel sides tapering to rounded ends. In vitro growth of *Legionella* from clinical specimens requires a source of amino acids, iron, and L-cysteine, such as buffered charcoal yeast extract (BCYE) agar enriched with α-ketoglutarate.[5] After recovery on artificial media, *Legionella* stain as gram-negative bacilli.

Pathogenesis and Epidemiology

Legionella species are facultative intracellular pathogens capable of surviving and multiplying both in mammalian macrophages and monocytes (e.g., in the alveolar spaces) to cause human infection and in free-living amebas to survive in the environment. After internalization of bacteria in an antibody-independent process, the bacterial phagosome becomes covered by smooth vesicles that likely originate from the endoplasmic reticulum. This results in evasion of the endocytic pathways and avoidance of phagosomal acidification and fusion with lysosomes that otherwise would result in bacterial digestion. The Dot/Icm type IV secretion system encoded by genes in *L. pneumophila* is critical for evasion of killing, intracellular multiplication, and virulence.[9] The pathogenesis of Pontiac fever may involve a host response to endotoxin from lipopolysaccharide of *Legionella* or other gram-negative bacteria without multiplication of *Legionella* in the host.[10]

L. pneumophila is not transmitted from human to human. Infection most commonly results from the inhalation or aspiration of contaminated aerosol from environmental or aquatic sources.[11–15] *Legionella* spp. naturally occur in freshwater habitats such as lakes, rivers, and ground water. From these sources organisms gain entry into water systems of buildings, including hospitals. These bacteria grow optimally at 35°C–37°C but thrive in warm water (temperature range, 30°C–54°C) and generally are killed at temperatures above 60°C.[5,6] *Legionella* have been found in cooling towers and evaporative condensers, water heaters, plumbing systems, shower heads, respiratory therapy devices, air conditioners, whirlpool spas, and humidifiers.[6] Survival and persistence of these nutritionally fastidious organisms in the environment make it likely that protozoa, particularly amebas, act as reservoirs in water sources. Legionnaires' disease due to *L. longbeachae* has been associated with exposure to potting soil.[7]

Nosocomial infections and hospital outbreaks due to *L. pneumophila* or other *Legionella* spp. have occurred. The source generally is water, most commonly the hot water supply.[12–15] Strains associated with nosocomial infection can colonize water supplies over long periods.[13] Community-acquired outbreaks of legionnaires' disease almost always are due to *L. pneumophila*,[7] and such outbreaks frequently have been associated with a nearby cooling tower, as proved by isolation of the same strain as confirmed by DNA-based molecular typing from infected patients, the cooling tower, and aerosols from the cooling tower.[11] In addition, outbreaks have been associated with other sources of water, including whirlpool baths, decorative fountains, and ultrasonic mist machines used to humidify fresh produce in a grocery store.[6] Sporadic cases of legionellosis have been linked to home water heaters, particularly electric water heaters. In 40% of 20 sporadic cases studied, isolates identical to the infecting isolates were found in the potable water at the patient's home or workplace, or at an ambulatory medical facility visited by the patient.[14]

Most cases of legionnaires' disease occur in susceptible elderly or middle-aged adults. Based on the outbreak in Philadelphia, the incubation period is estimated to range from 2 to 10 days, with a mean of approximately 7 days.[1] Risk factors for infection in adults include cigarette smoking, alcoholism, chronic lung or heart disease, and treatment with high doses of corticosteroids or other immunosuppressive drugs, including those given to prevent rejection of transplanted organs, and tumor necrosis factor-α antagonists.[1,6,16] Legionellosis is an occasional cause of pneumonia in adults with acquired immunodeficiency syndrome, in whom it accounts for 1% to 3% of pneumonia episodes.[17] *L. pneumophila* has caused pneumonia in patients infected with 2009 pandemic influenza A:H1N1.[18] In the United States, higher numbers of cases are reported during the warmer months.[19]

Legionellosis remains a rarely reported infection in children. Despite a 53% increase in rate of legionellosis from 2003 to 2012, only 8 cases (0.22%) of legionellosis reported to the Centers for Disease Control and Prevention in 2012 were patients younger than 15 years.[19] *Legionella* bacteria probably are responsible for 1% to 5% of episodes of pneumonia in immunocompetent children.[20–23] Infection is being recognized increasingly in neonates related to healthcare-associated contaminated water sources that include potable water for preparing infant formula, water tubs for water births, and humidifiers in nurseries.[24–27] In pediatric legionellosis, risk factors for serious infection are neonatal age group, immune compromise as a result of cancer or organ transplantation and their treatments, corticosteroid or adrenocorticotropic hormone therapy, primary immunodeficiency, or underlying lung disease[12,28–31] (Table 177.1). Most published cases of legionellosis in children are hospital acquired, but this may represent a reporting bias.[29] In a review of legionellosis in children, the overall mortality rate was 33%, with the highest mortality rates in immunosuppressed children and children younger than 1 year.[29]

TABLE 177.1

Legionella Pneumonia in Children

Patient Population	Features
Neonates	Previously healthy or premature infants; can have bronchopulmonary dysplasia, corticosteroid therapy, or congenital heart disease; frequently nosocomial; typically healthcare associated, related to contaminated water source, including water birth; frequently unsuspected and diagnosed at autopsy
Immunocompetent children hospitalized with pneumonia	Mild to moderate severity; recovery can occur without the use of effective antibiotics
Children with underlying pulmonary disease or receiving mechanical ventilation	Nosocomial source is common
Immunocompromised children: corticosteroid or ACTH treatment, anticancer or antiorgan rejection therapies, congenital immune deficiency (severe combined immunodeficiency, chronic granulomatous disease)	Nosocomial or community-acquired; onset often within weeks of transplantation, beginning ACTH therapy, or induction chemotherapy for malignancy

ACTH, adrenocorticotropic hormone.

Clinical Manifestations

Legionella infection can be classified into the following four categories: (1) pneumonia; (2) subclinical infection; (3) nonpneumonic disease, referred to as *Pontiac fever;* and (4) extrapulmonary inflammatory disease. The most important clinical infection in children and adults is pneumonia, which manifests as an acute febrile illness with cough and often with respiratory distress.[29] Initially, nonpulmonary symptoms can predominate and include chills, abdominal pain, myalgia, confusion, malaise, anorexia, and diarrhea. Extrapulmonary manifestations, particularly confusion and diarrhea, are common, but the combination of pulmonary and extrapulmonary clinical findings is not sufficiently specific to differentiate *Legionella* pneumonia from community-acquired or nosocomial pneumonia of other etiologies.[32] The nonproductive cough suggests atypical pneumonia, which requires differentiation from *Mycoplasma pneumoniae,* viral, and *Chlamydophila pneumoniae* infections.

Chest radiograph shows patchy alveolar rather than interstitial infiltrates. In most cases, pulmonary disease is unilateral. Pulmonary nodules, with or without cavitation, or cavitating pneumonia can develop, particularly in immunocompromised hosts.[28,29,33,34] Pleural effusion occurs, with an incidence similar to that of other bacterial pneumonias.[34] Progressive respiratory distress and respiratory failure can develop over a period of several days. Copathogens are recovered from respiratory tract specimens in only a few cases.[18,31] *Legionella* infection causing fever and pulmonary nodules is relatively common in adult renal or cardiac transplant recipients and occurs within several weeks of transplantation. Alternatively, these patients may have prodromal symptoms of malaise, myalgia, and headache followed by an abrupt onset of symptoms indicative of pneumonia: dyspnea, cough, and pleuritic chest pain.[35,36]

Serious or fatal *Legionella* pneumonia is being reported increasingly in neonates.[24–27] Many infants were born at term and manifested septicemia, pneumonia, or both, but several were born prematurely or had congenital heart disease.[24] An outbreak of 11 cases of *Legionella* pneumonia in term neonates from a single nursery included 3 fatal cases; evaluation implicated a *Legionella*-contaminated humidifier in the nursery.[25] At least 4 cases of *L. pneumophila* pneumonia with 2 fatalities have been reported after water birth at home or in a hospital birthing pool.[27] The mortality rate of neonatal legionellosis is high, and survival correlates with macrolide/azalide treatment.

Infections in immunocompromised hosts and neonates represent the most severe form of pediatric disease. At the other end of the clinical spectrum, community-acquired pneumonia due to *Legionella* in healthy children usually resolves without effective antibiotic therapy.[20–22] Subclinical infection also occurs, as evidenced by increasing seroprevalence with age,[20,21,23] and by antibody rises in the absence of recognized episodes of pneumonia.

Epidemic, nonpneumonic disease, also known as *Pontiac fever*, is characterized by a high attack rate in exposed individuals. After a short incubation period of 12 to 48 hours, infection is characterized by the abrupt onset of an influenza-like illness without pneumonia. Prominent signs and symptoms include fever, malaise, myalgia, and cough. The illness is self-limited, although a cluster of cases with respiratory compromise is described.[37] The initial outbreak of Pontiac fever was associated with *L. pneumophila* serogroup 1, but other *Legionella* spp. have been associated with outbreaks.[10]

In adults, a spectrum of extrapulmonary *Legionella* infections have been documented, including sinusitis, perirectal abscess, pyelonephritis, peritonitis, pancreatitis, pericarditis, and endocarditis.[32] In children, extrapulmonary sites of infection in the liver, spleen, and brain have been documented at autopsy.[24,30] Localized extrapulmonary infection, such as infection of postoperative wounds after wound irrigation with *Legionella*-contaminated tap water, also can occur.

Laboratory Diagnosis

Nonspecific laboratory abnormalities in legionellosis can include leukocytosis with a left shift of neutrophils, hyponatremia, proteinuria, or elevated serum concentrations of hepatic enzymes. In adults, hyponatremia is significantly more frequent in the initial stage of legionellosis than in pneumonia of other etiologies.

A specific laboratory diagnosis can be established by (1) isolation of the organism in culture; (2) detection of organisms, bacterial antigens, or nucleic acids in clinical specimens; or (3) documentation of a serologic response to the organism.[5,6] Although culture is the gold standard for diagnosis, only ~5% of diagnoses are based on culture, and most diagnoses are based on urine antigen testing that primarily detects *L. pneumophila* serogroup 1.[6] Compared with culture, the common use of urine antigen assays for diagnosis may have biased the distribution of *Legionella* spp. and serogroups causing disease.[6] A clue to suspect legionellosis is the presence of characteristic neutrophilic inflammatory response without bacteria on a gram-stained preparation of lower respiratory tract secretions because *Legionella* stain poorly with Gram stain. However, the absence of the failure to produce sputum or absence of neutrophils in specimens does not exclude the diagnosis[38]

Microscopic screening protocols of sputa (to evaluate for the presence of leukocytes as a measure of adequacy of the specimen for bacterial culture) are not useful for selecting samples to be cultured for *Legionella. Legionella* spp., particularly *L. micdadei*, may stain with acid-fast stain[39]; modified acid-fast stain can be useful.

Culture

Legionella is best grown on BCYE agar containing 0.1% *α*-ketoglutarate and L-cysteine supplemented with dyes to aid identification of colonies and antimicrobial agents such as vancomycin, polymyxin B, and anisomycin to inhibit overgrowth by other bacteria and yeast; incubation is at 35°C in a humidified atmosphere containing 2.5% CO_2.[5,6] Heating or washing sputum specimens with acid before inoculation reduces contamination and enhances recovery.[5,6] Although BCYE agar is available commercially, some lots exhibit poor clinical performance. Colonies take ≥3 days to appear and exhibit ground-glass morphology. *L. pneumophila* has been isolated from both aerobic and anaerobic broth blood culture systems, but only after blind subculture. Laboratory personnel should be apprised when legionellosis is suspected.

Bacterial Detection

Tests for antigen detection in urine are used most frequently to diagnose legionellosis. Detection of *L. pneumophila* serogroup 1 lipopolysaccharide antigens in urine by commercially available immunochromatographic membrane assays or enzyme immunoassay is possible as early as a few days after the onset of infection. These assays have high sensitivity (90%) and specificity (80%).[5,6,40] Sensitivity is higher in patients with more severe pneumonia and when urine is concentrated before testing and when incubation time is prolonged.[41,42] In addition to detection of *L. pneumophila* serogroup 1, a positive result sometimes is noted in patients infected with *L. pneumophila* non–serogroup 1 or other *Legionella* spp.[43,44] Antigenuria typically is prolonged beyond resolution of clinical infection and should not be used to judge adequacy of therapy.[45] In one outbreak, urine antigen assay was useful in diagnosing Pontiac fever.[46]

Detection of organisms on smears of respiratory tract secretions by direct (or indirect) immunofluorescence assay) using polyclonal or monoclonal antibody is no longer performed in most laboratories because of required technical expertise and test performance similar to urine antigen tests.

Nucleic acid amplification–based assays to detect DNA from all *Legionella* spp. (e.g., assays targeting a conserved segment of the ribosomal RNA genes for the 5S and 16S subunits) or *L. pneumophila* (e.g., assays targeting the macrophage inhibitor protein *mip* gene in respiratory specimens) have been developed. These assays have a sensitivity comparable with or superior to that of culture or urinary antigen detection and have excellent specificity, but commercial assays are not available widely.[5,6,47,48]

Serology

Serology is rarely used to diagnose *Legionella* infection because of the requirement for a convalescent specimen and the limited validation of tests for infection other than due to *L. pneumophila* serogroup 1. Serologic confirmation requires a fourfold rise in antibody titer to ≥1 : 128 in paired specimens, typically taken 4 to 8 weeks or longer apart.[5,6,49] An indirect immunofluorescence assay (IFA) is the gold standard for serologic testing. In the setting of sporadic disease, neither a single elevated IFA titer nor measurement of immunoglobulin M antibody is useful for diagnosis.[5,6,49] “Seroconversion” occasionally is due to cross-reaction after infection with another organism such as *Citrobacter freundii, Bacteroides fragilis, Chlamydophila psittaci,* or *Coxiella burnetii.*[50,51] A false-positive serologic test is frequent in patients with cystic fibrosis and is related to cross-reaction with *Pseudomonas* spp.[52] Seroconversion has been documented in several young children with legionellosis.[21,53,54] Most cases of Pontiac fever have been diagnosed using serologic tests.

Treatment

Options for antibiotic treatment of legionellosis are summarized in Table 177.2. Based on clinical experience, intravenously administered azithromycin is the antibiotic of choice for the treatment of *Legionella* infection in healthy children, whereas levofloxacin is the antibiotic of choice for the treatment of *Legionella* infection in immunocompromised or severely ill children. Fluoroquinolone antibiotics, unlike erythromycin, are bactericidal for *Legionella* and therefore may be superior to macrolide/azalide therapy, at least in immunocompromised patients.[55,56] However, here have been no randomized clinical treatment trials comparing a fluoroquinolone with a macrolide or azalide. In a metaanalysis of 12 observational studies in adults with *Legionella* pneumonia, patients treated with a fluoroquinolone, primarily levofloxacin, had a shorter hospital stay and a trend toward a lower mortality rate, higher clinical cure rate, and lower rate of complications than patients treated with a macrolide or azalide.[57] In contrast, in a retrospective cohort analysis of 3152 adults hospitalized in 427 US hospitals with a diagnosis of *Legionella* pneumonia, among adults treated with either a macrolide or a fluoroquinolone there were no differences in crude or adjusted mortality, hospital length of stay, development of *Clostridium difficile* colitis, or total hospital cost.[58]

Antimicrobial Agent(s)	**Pediatric**	**Adult**	**Pediatric**	**Adult**
FIRST CHOICE				
Normal host: azithromycin[b]	10 mg/kg every 24 hr (maximum, 500 mg/day)	500 mg every 24 hr	10 mg/kg every 24 hr (maximum, 500 mg/day)	500 mg every 24 hr
Immunocompromised host or severely ill: levofloxacin[c]	Not approved for patients younger than 18 yr for routine use. Age 6 mo–4 yr: 10 mg/kg every 12 hr; 5–17 yr: 10 mg/kg every 24 hr (maximum, 750 mg/day)	750 mg every 24 hr	Not approved for patients younger than 18 yr for routine use. Age 6 mo–4 yr: 10 mg/kg every 12 hr; 5–17 yr: 10 mg/kg every 24 hr (maximum, 750 mg/day)	750 mg every 24 hr
SECOND CHOICES				
Clarithromycin	Not available	Not available	7.5 mg/kg every 12 hr (maximum, 500 mg every 12 hr)	500 mg every 12 hr
Ciprofloxacin	Not approved for patients younger than 18 yr for routine use; 10 mg/kg	400 mg every 8 hr	Not approved for patients younger than 18 yr for routine use; 15	750 mg every

	every 8 hr (maximum, 400 mg every 8 hr)		mg/kg every 12 hr (maximum, 750 mg every 12 hr)	12 hr
Erythromycin[d]	40 mg/kg/day	1 g every 6 hr	40 mg/kg/day	500 mg every 6 hr
POTENTIAL ALTERNATIVES				
Moxifloxacin	Not approved for patients younger than 18 yr	400 mg every 24 hr	Not approved for patients younger than 18 yr	400 mg every 24 hr
TMP-SMX	5 mg TMP/kg every 8 hr	160 mg TMP every 8 hr	5 mg TMP/kg every 8 hr	160 mg TMP every 12 hr
Doxycycline	2 mg/kg every 12 hr (maximum, 100 mg/dose)[d]	200 mg once; 12 hr later start 100 mg every 12 hr	2 mg/kg every 12 hr (maximum, 100 mg/dose)[e]	100 mg every 12 hr

[a] The duration of therapy is 14−21 days, except for therapy with azithromycin, which is 5–10 days.

[b] Some patients have been treated with an initial loading dose of 20 mg/kg (maximum, 1000 mg) followed 24 hours later by the dose in the table.

[c] In severely ill patients, combination therapy with levofloxacin and azithromycin can be considered, but clinical experience is very limited.

[d] Erythromycin is likely to be less effective than azithromycin. Intravenous erythromycin doses up to 100 mg/kg/day have been administered to children without difficulty.

[e] Generally not prescribed in children younger than 9 years of age.

TMP-SMX, trimethoprim-sulfamethoxazole.

Azithromycin is preferred over erythromycin intravenously because of azithromycin's ease of administration (one daily dose, smaller fluid volume, and less vein injury), superior activity in vitro and in an animal model of infection, higher lung levels, and better intracellular penetration.[56,59] Oral azithromycin can be substituted after definite clinical response, to complete a 5- to 10-day course of therapy. The longer duration of therapy is used for immunocompromised patients. The addition of rifampin has not been demonstrated to enhance the efficacy of azithromycin or levofloxacin, and some treated patients have developed elevated serum bilirubin levels.[56] When treating recipients of transplanted solid organs, caution is required because azithromycin (and erythromycin) inhibit the metabolism of cyclosporine.[35]

Many antibiotics show activity against *Legionella* in vitro, but only antibiotics with intracellular penetration are effective. Testing of antibiotics in vitro against intracellular *Legionella* in a *Legionella*-infected cell line or in vivo (e.g., with a guinea pig model of infection) may more accurately predict the effectiveness of an antibiotic against human infection.[56,59] For example, β-lactam antibiotics are active in vitro but are ineffective in treating *Legionella* pneumonia. Clindamycin and aminoglycosides also are ineffective.[7] Doxycycline or trimethoprim-sulfamethoxazole has been used successfully in some patients. In a few cases of infection with *L. micdadei,* patients who failed erythromycin treatment responded to trimethoprim-sulfamethoxazole.

Prevention

Primary prevention of *Legionella* infection in healthcare facilities involves testing of water and eradication of contamination before cases occur. Efforts to prevent healthcare-associated *Legionella* infection where cases have occurred or where *Legionella* has been detected in the water systems are directed toward treating water distribution systems to inactivate or remove organisms.[60,61] Methods include (1) copper-silver ionization by electrolysis; (2) chlorine dioxide, monochloramine, or hyperchlorination followed by continuous chlorination (to achieve 1–2 mg of free residual chlorine per liter); (3) periodic superheating to temperatures greater than 60°C and flushing of distal sites (with or without maintenance of the water temperature above 50°C); (4) point-of-use filtration; (5) ultraviolet light; or a combination of methods.[62] Copper-silver ionization may be the method of choice as the best studied method,[63,64] although this requires relatively expensive equipment, does not reliably eradicate *Legionella* from the water system,[65] and may lose effectiveness after several years because of the emergence of *Legionella* strains tolerant of silver ions.[66] Over time, continuous chlorination can cause corrosion of pipes and leakage, and chlorination is associated with the production of carcinogenic trihalomethane byproducts.[7,62] Superheating is advantageous in that it can be instituted rapidly to interrupt an outbreak. In one hospital with a high incidence of nosocomial *Legionella* pneumonia in renal transplant recipients, prophylactic erythromycin therapy was successful.[67] A vaccine is not available.

Key Points

Epidemiology, Clinical Features, and Diagnosis of *Legionella* Infection

Epidemiology

- Risk groups
    - Elderly
    - Immunosuppressed adults and children, particularly organ transplant recipients
    - Adults and children treated with corticosteroids
    - Adults and children with chronic lung disease
    - Neonates
- Bacterial reservoir: freshwater habitats and potable water
- Mode of transmission: inhalation or aspiration of *Legionella*-contaminated water
- Pediatric infections frequently are nosocomial

Clinical Features

- Pneumonia is the most common manifestation.
- Clinical manifestations: fever, nonproductive cough, respiratory distress
- Chest radiograph: patchy alveolar infiltrates, usually unilateral, at times nodular

Diagnosis

- Urine antigen detection is the most practical diagnostic test.

▪ High specificity

▪ Sensitive for *Legionella pneumophila* serotype 1

▪ Occasionally detects other serotypes or species

Rickettsia rickettsii (Rocky Mountain Spotted Fever)

Christopher D. Paddock, Gerardo Alvarez-Hernández

Description of the Pathogen

Rickettsia rickettsii, the etiologic agent of Rocky Mountain spotted fever (RMSF), is a small, obligately intracellular, gram-negative, rod-shaped organism that is among the most pathogenic of all known bacteria. Although *R. rickettsii* can infect several different cell types, its primary targets in mammalian hosts are the endothelial cells lining capillaries, arterioles, and venules of all major tissues and organ systems (Fig. 178.1).[1] Damage to endothelium of the dermis, skeletal muscle, and vital organs such as brain, heart, lungs, kidneys, and gastrointestinal tract results in the systemic manifestations characteristically observed in people with RMSF.

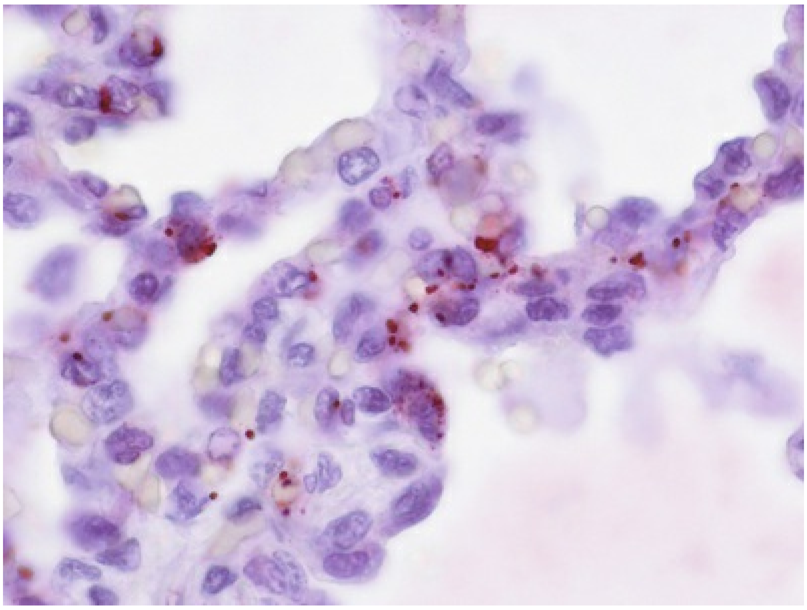

FIGURE 178.1 Immunohistochemical stain demonstrating *Rickettsia rickettsii* bacteria *(red)* infecting endothelial cells of alveolar capillaries in the lung of a 5-year-old child with fatal Rocky Mountain spotted fever. Immunoalkaline phosphatase with naphthol fast-red and hematoxylin counterstain; original magnification, ×158.

Ku70, a high molecular weight protein that is expressed at the plasma membrane of mammalian endothelial cells, monocytes, and macrophages, is believed to serve as a receptor for cell invasion by *R. rickettsii*.[2] Several rickettsial outer membrane proteins, including rOmpB (sca5), rOmpA (sca0), and sca1, are involved in the attachment to and subsequent endocytosis by the mammalian host cell. When inside the cell, *R. rickettsii* rapidly escapes a transient invasion vacuole to reside freely in the cytoplasm, where it replicates by binary fission. *R. rickettsii* is capable of intracellular movement that involves rickettsia-mediated polymerization of host-cell actin.[3,4] Rickettsiae that collide with the plasma membrane of the host cell create protrusions that extend into and become internalized by adjacent cells or may be released into the extracellular space and attach to neighboring cells.[5,6] *R. rickettsii* severely damages the plasma membrane of endothelial cells and disrupts the structural organization of intracellular organelles and cytoskeleton. Oxidative injury to host cells leads to diffuse microvascular injury and fluid leakage into extravascular spaces.[7–11] Different strains of *R. rickettsii* produce varying levels of injury to cultured human endothelial cells; however, these differences have not been characterized in vivo, and severe or fatal disease has resulted from infections with at least 4 genetically distinct strains of *R. rickettsii*.[12,13] The genetic basis for the virulence of *R. rickettsii* is not well understood.[14,15]

Epidemiology

RMSF occurs throughout much of the Western Hemisphere and is maintained in nature by several species of ticks and mammals. Humans are incidental hosts and become infected with *R. rickettsii* from the bite of an infected tick. Throughout much of the United States, *Dermacentor variabilis* (the American dog tick) and *Dermacentor andersoni* (the Rocky Mountain wood tick) are considered primary tick vectors. *Rhipicephalus sanguineus* sensu lato (the brown dog tick) is also a primary vector in some regions, particularly in northern and central Mexico and the southwestern United States.[16–18] In South America, other hard tick species, including *Amblyomma sculptum* and *Amblyomma aureolatum*, are important vectors.[19]

RMSF is a nationally notifiable disease in the US, and the reported incidence of RMSF and other tickborne spotted fever group rickettsioses, including *Rickettsia parkeri* rickettsiosis and *Rickettsia* sp. 364D rickettsiosis, increased markedly during the past 15 years. During 2000–2007, the reported incidence of these infections rose from 1.7 to more than 7 cases per million persons.[20] During 2008–2012, the estimated average annual incidence of all spotted fever group rickettsioses was 8.9 cases per million persons, with 63% of all reports originating from Arkansas, Missouri, North Carolina, Oklahoma, and Tennessee (Fig. 178.2). Most US cases are reported during April–September, corresponding with periods of increased host-seeking activity of adult-stage *Dermacentor* ticks.

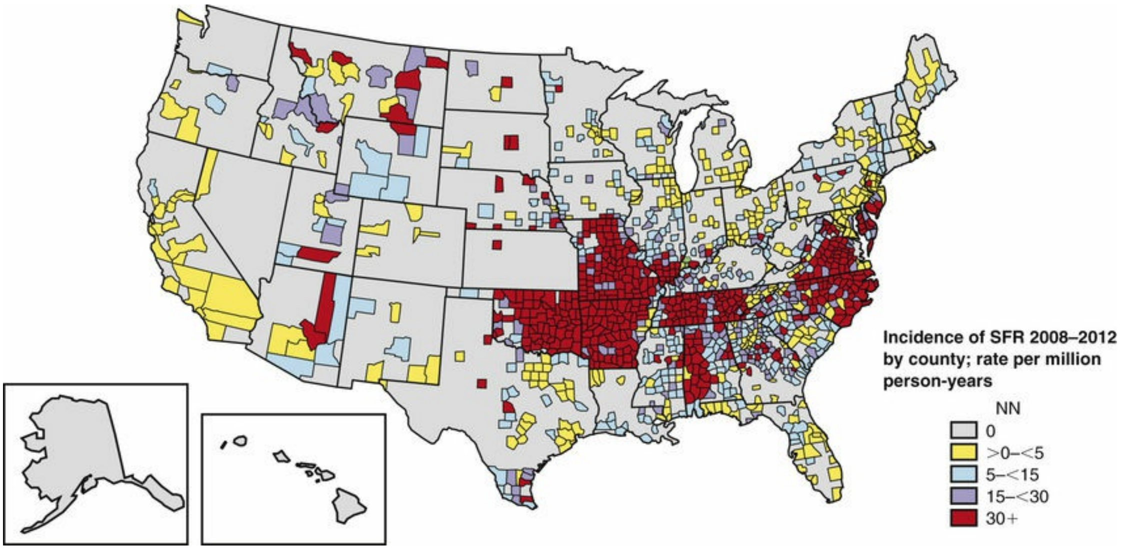

FIGURE 178.2 Reported incidence rate of spotted fever group rickettsiosis, by county—United States, 2000–2013, per 1,000,000 persons per year.[26] The reporting category “Rocky Mountain spotted fever” (RMSF) was changed in 2010 to “spotted fever rickettsiosis” (SFR), and current passive surveillance does separate RMSF from other spotted fever group rickettsiosis. (From Drexler NA, Dahlgren FS, Heitman KN, et al. National surveillance of spotted fever group rickettsioses in the United States, 2008−2012. Am J Trop Med Hyg 2016;94:26−34.)

Surveillance data indicate that RMSF occurs more frequently in older adults than in children.[20–22] On a national scale, age-specific incidence rates of RMSF are highest for persons aged 60 to 69 years; nonetheless, in one recently characterized outbreak, approximately 50% of 205 RMSF patients were younger than 10 years.[23] In general, case-fatality rates are disproportionately higher among young children compared with adults. During 1983–2007, approximately 15% of all reported fatal cases of RMSF were in children younger than 10 years,[24,25] and from 2008–2012, case-fatality rates in this cohort were approximately 5 times greater than all other age groups combined.[26] Prevalence of anti−*R. rickettsii* antibodies appears to increase with age as a function of increased risk for exposure to *R. rickettsii* or other spotted fever group *Rickettsia* spp. over a lifetime.[27,28] A survey of approximately 2000 children from the southeast and south central US reported a 12% prevalence of antibodies reactive with *R. rickettsii* using routinely available serologic assays but may include infections caused by *Rickettsia* spp. other than *R. rickettsii*.[29,30]

Most cases of RMSF occur sporadically, but family and community clusters can occur and are related to *R. rickettsii* infections in focal tick populations around a home, neighborhood, or park.[16,31–36] As a result, multiple infections can occur simultaneously or sequentially in the same household after identification of an index case.[31]

Clinical Manifestations

RMSF can be difficult to diagnose clinically in its early stages.[37] Although most patients seek care within the first 3 days after onset of fever, prodromal signs and symptoms are nonspecific, and even in areas where disease awareness is high, 60% to 86% of patients with RMSF are not diagnosed correctly on their first visit for medical care.[37–39] The early signs, symptoms, and laboratory features of RMSF often are insufficient to differentiate this disease from other viral or bacterial illnesses that present as an acute sepsis syndrome.[23] Epidemiologic clues such as history of outdoor activity, contact with animals (particularly dogs) or exposure to ticks may be helpful; however, a history of a tick bite or exposure is absent in 40% to 50% of patients included in several US pediatric case series (Table 178.1).[37,40,41]

NR, not reported.

Most patients develop symptoms within 2 to 10 days after the bite of an infected tick.[44,45] The disease begins with abrupt onset of fever often accompanied by severe frontal headache, nausea or vomiting, and generalized myalgia. The temperature generally is high and often >40°C. Headache, which may be less commonly noted in young children, is often intractable to therapy. Other findings recorded with varying frequency in pediatric case series include calf tenderness, abdominal pain, irritability, splenomegaly, conjunctivitis, periorbital edema, and peripheral edema, particularly involving the dorsum of the hands (Fig. 178.3A and B; see Table 178.1;).[37,40–46]

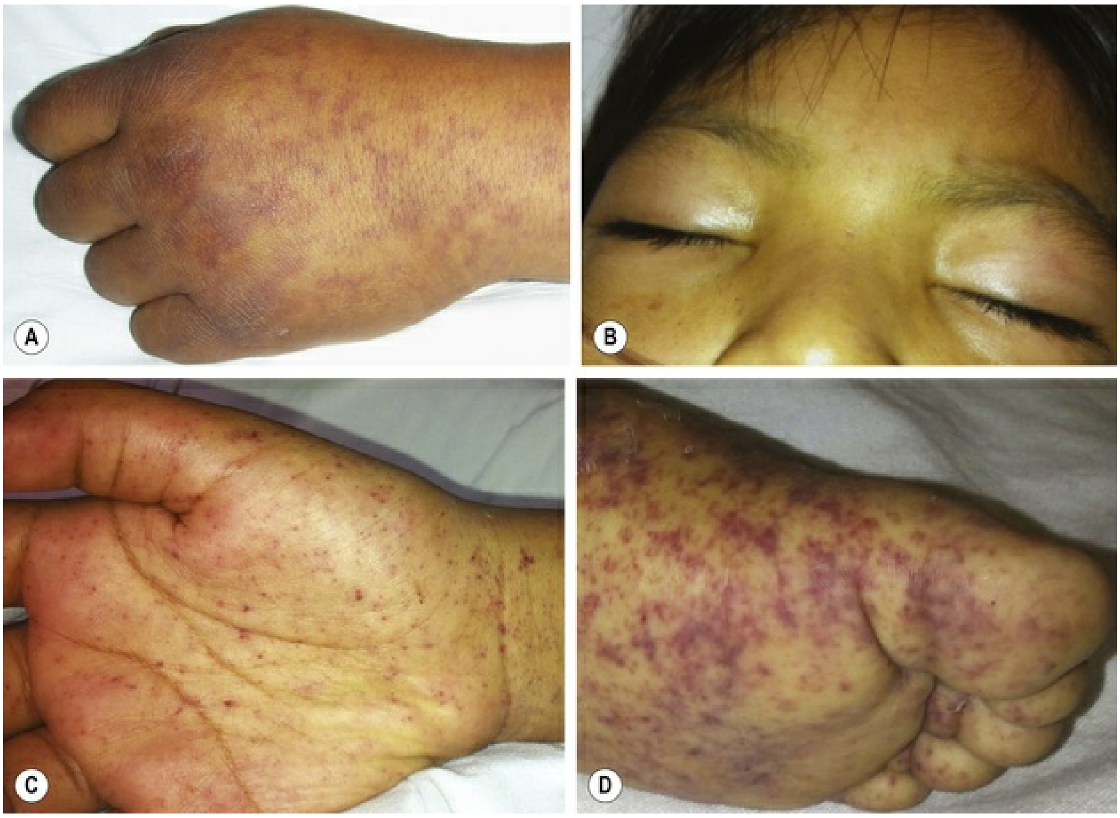

FIGURE 178.3 Clinical signs identified in children with Rocky Mountain spotted fever. (A) Edema of the dorsum of the hand. (B) Periorbital edema. (C and D) Petechial rashes involving the palm and sole.

A generalized maculopapular rash, consisting of discrete, 1- to 5-mm blanching macules, is considered a hallmark feature of RMSF. However, the rash may be absent until 2 to 5 days after fever onset, especially in older patients, and may be difficult to identify in patients with dark skin.[45–48] Therefore, clinicians must not await appearance of the distinctive rash to establish a diagnosis and initiate therapy. In most cases, the rash begins on the wrists, ankles, and forearms and then spreads centrally to involve the legs, buttocks, trunk, and face. In more advanced cases of disease, the rash frequently involves the palms and soles (Fig. 178.3C and D). In some patients, the mucous membranes of the palate and pharynx also can be affected.[37,39] With progression of disease, the rash becomes more petechial, and individual lesions often enlarge and coalesce to form ecchymoses. In approximately 10% of patients, the rash is evanescent, atypical in distribution, or entirely absent.[33,47–49]

RMSF can progress rapidly to catastrophic disease involving multiple organ systems. Severe infections often are characterized by concomitant life-threatening manifestations that may include acute respiratory distress syndrome, first-degree atrioventricular block, cardiac failure, disseminated intravascular coagulation, gangrene, acute renal failure, seizure, coma, or tonsillar herniation.[23,33,42,43,50–52] Central nervous system disease generally occurs later in the illness and manifests as parenchymal edema, perivascular infarcts, and leptomeningeal vasculitis. Computed tomography is generally unremarkable, although images may demonstrate sulcal effacement consistent with generalized edema, or low-density white-matter foci consistent with infarcts. Magnetic resonance imaging is generally more distinctive and may identify punctate perivascular infarcts in the deep white matter, referred to as a "starry sky" pattern (Fig. 178.4).[53]

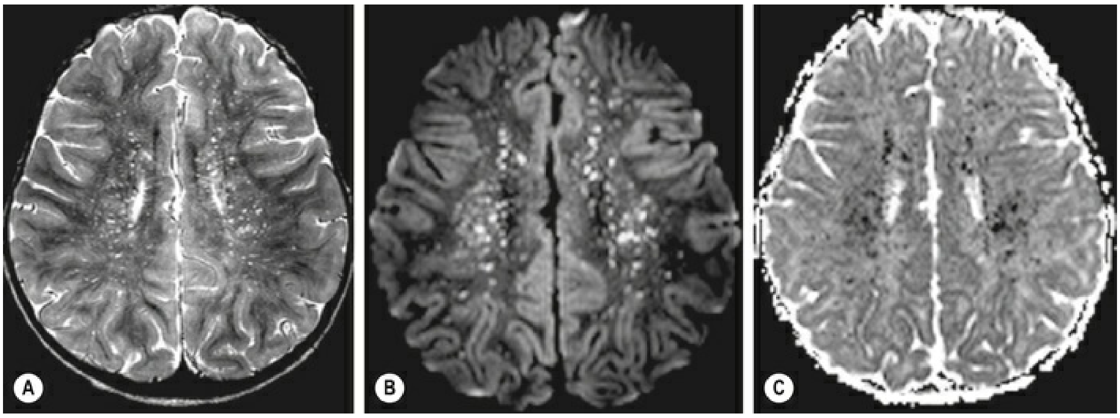

FIGURE 178.4 Axial magnetic resonance imaging (MRI) of the brain of a 2-year-old child with Rocky Mountain spotted fever and altered mental status. (A) T2-weighted MRI demonstrating numerous, punctate, hyperintense foci scattered bilaterally in the subcortical and deep white matter in a perivascular distribution. (B) Diffusion-weighted image at same level as A showing increased signal corresponding to T2 white-matter lesions. (C) Corresponding ADC map confirms restricted diffusion. (Courtesy of Sumit Pruthi, MD. From Crapp S, Harrar D, Strother M, et al. Rocky Mountain spotted fever: "starry sky" appearance with diffusion-weighted imaging in a child. Pediatr Radiol 2012;42:499−502.)

During the years immediately preceding the introduction of effective antirickettsial therapies, an estimated 19% of all US patients infected with *R. rickettsii* died from RMSF.[54] With advances in treatment and medical care, US deaths attributable to RMSF declined considerably; nonetheless, from one well-characterized US outbreak during 2002–2011 involving approximately 200 patients, the case-fatality rate was 7%.[52] In many countries in Latin America, case-fatality rates are much higher, including recent estimates from pediatric case series in Mexico that documented fatal outcomes in 20% to 55% of infected children.[42,43] Most RMSF deaths are attributable to delayed diagnosis and failure to initiate specific antimicrobial therapy within the first 5 to 6 days of illness.[43,52,55–58] Timely administration of appropriate therapy is critical because at least one half of all deaths occur within 8 days of disease onset.[15,59] Patients with glucose-6-phosphate dehydrogenase deficiency typically experience severe and accelerated illness that often culminates in death in ≤5 days.[60]

Laboratory Findings and Diagnosis

Decisions to treat are guided principally by an overall awareness of the disease and by epidemiologic clues garnered during a careful history.[58,61] Routine laboratory tests may reveal hyponatremia, hypoalbuminemia, anemia, or thrombocytopenia to reflect vascular injury and increasing vascular permeability.[9] Low serum sodium levels or platelet counts (often <100,000/mm^3) occur in 50% to 60% of all patients. The white blood cell count is usually normal during the first several days of the infection, but leukocytosis occurs in 40% to 80% of patients with severe disease.[43]

The diagnosis can be confirmed by serology, polymerase chain reaction assays, immunohistochemical staining of tissue specimens, or isolation of *R. rickettsii* in cell culture; nonetheless, the decision to initiate appropriate antibiotic therapy should never be delayed pending results of laboratory testing. The indirect immunofluorescence antibody (IFA) assay is the recommended method for detecting antibodies to *R. rickettsii*; nonetheless, in approximately 50% of patients, diagnostic levels of antibody are not detectable by this method until the second week of disease.[62,63] Most patients come to medical attention during the first 3 days after the onset of illness, and the initial serum sample in these patients frequently is negative. Evaluation of a second serum sample, obtained 2 to 4 weeks later, typically reveals a fourfold or greater change in antibody titer between the initial and second specimen and is necessary to serologically confirm a diagnosis. A single IFA serum titer of ≥1 : 64 suggests only a probable diagnosis.[61] Enzyme immunoassay (EIA) techniques generally are limited in their ability to confirm active infection. IFA and EIA assays that detect immunoglobulin G (IgG) antibodies specifically are preferred over assays that measure IgM antibodies because the latter often are associated with nonspecific reactivity and should not be interpreted in the absence of an IgG antibody titer to *R. rickettsii*.[64]

Immunohistochemical and immunofluorescence staining of antigens in formalin-fixed, paraffin-embedded biopsy specimens of rash lesions or autopsy tissues are diagnostic methods that provide direct observation of the pathogen in the appropriate histopathologic context. Immunostaining of tissue is most likely to reveal organisms within the first 48 hours after initiating appropriate antibiotic therapy. These techniques have been used to diagnose nonfatal and fatal cases of RMSF.[15,60,65–67]

Molecular detection of *R. rickettsii* in whole blood generally is insensitive during the early stages of illness because of low density of circulating organisms before advanced disease.[68,69] Polymerase chain reaction assay generally is more useful for detecting *R. rickettsii* in skin biopsy or autopsy tissue specimens. *R. rickettsii* requires cell culture for microbiologic isolation and should be attempted only in laboratories equipped with biosafety level 3 facilities.[70]

Treatment

RMSF is a life-threatening illness, and appropriate antimicrobial therapy must be initiated quickly and empirically on the basis of clinical and epidemiologic findings. Clinicians must treat presumptively and should never delay or stop therapy while waiting for the results of a confirmatory test, or on the basis of an initially negative test result. Tetracycline-class antibiotics, most often doxycycline, are the treatment of choice. Patients treated with tetracycylines within the first 5 days of symptoms are significantly less likely to be hospitalized, require admission to an intensive care unit, or die than people treated later in the course of disease with the same tetracycline antibiotic or treated with antibiotics with no efficacy against *R. rickettsii*.[43,52,56,59] For children of any age, doxycycline is the drug of choice.[61,71] For children weighing >45 kg

(100 lb), the recommended treatment is 100 mg every 12 hours. For children <45 kg, doxycycline is given at a dose 2.2 mg/kg every 12 hours. Both oral and intravenous formulations are available in the US. Doxycycline generally is preferred over other tetracyclines because of its reduced phototoxicity, safety in patients with renal insufficiency, lower binding to calcium, and longer plasma half-life. Most patients with uncomplicated RMSF defervesce within 24 to 48 hours after initiation of doxycycline therapy.[61] Resolution of symptoms typically occurs more slowly in patients with severe illness, particularly in people with damage to multiple organ systems; nonetheless, absence of clinical improvement within 72 hours should suggest the need to consider an alternate diagnosis. Therapy should be continued for at least 3 days after unequivocal evidence of clinical improvement is seen. The usual duration of treatment is 7 to 10 days.

Previous studies of children who received older tetracycline-class antibiotics (e.g., tetracycline, oxytetracycline, or chlortetracycline) during tooth crown calcification (which typically occurs before 8 years of age) linked these drugs with enamel hypoplasia and yellow, grey, and brown staining of permanent teeth. However, these observations have not been associated with the use of doxycycline, and several series examining the permanent teeth of children who received multiple courses of doxycycline while younger than 8 years, including those treated specifically for RMSF, have failed to demonstrate tooth staining, enamel hypoplasia, or tooth color differences attributable to this antibiotic.[72–74] Despite recommendations by the Centers for Disease Control and Prevention and the American Academy of Pediatrics Committee on Infectious Diseases that advocate the use of doxycycline as primary therapy for RMSF in children of all ages,[61,71] recent surveys indicate that many US healthcare providers remain reluctant to prescribe doxycycline to children younger than 8 years, even in areas where RMSF is endemic.[75–77] Clinicians should always prescribe doxycycline to children when a diagnosis of RMSF is suspected.

Chloramphenicol is the only other antibiotic with demonstrated clinical efficacy against *R. rickettsia*. However, this drug is no longer available in the oral form in the US. In addition, epidemiologic data suggest that patients treated with chloramphenicol have a higher risk for severe illness and death than children treated with a tetracycline.[57] In vitro evidence suggests that chloramphenicol may not be effective treatment of infections caused by *Ehrlichia* and *Anaplasma* spp., which often manifest similar clinical syndromes to RMSF. The pediatric parenteral dose of chloramphenicol is 50 to 100 mg/kg/day in four divided doses.[71] Reversible dose-related toxicities include bone marrow suppression and cardiomyopathy, and monitoring of serum levels is advisable when treating patients younger than 2 years, patients with hepatic disease, or people receiving therapy for more than 5 days. Peak serum levels of chloramphenicol should be maintained within the range of 10 to 30 μg/mL.

Prophylactic antibiotic therapy in asymptomatic people with a recent history of a tick bite is not warranted. Tetracyclines and chloramphenicol are bacteriostatic drugs; therefore, presumptive therapy before onset of symptoms is unlikely to prevent infection and may instead result in a delayed onset of disease.[78]

Special Considerations

Penicillins, cephalosporins, macrolides, aminoglycosides, and sulfa-containing antibiotics are ineffective in treating RMSF. Sulfonamides have no activity against *R. rickettsii* and may exacerbate the disease.[38,48,79,80] Some fluoroquinolones demonstrate strong bacteriostatic activity against *R. rickettsii* in vitro[81]; however, clinical efficacy data are not available on this class of drugs for the treatment of RMSF in humans. Tetracyclines generally are contraindicated in pregnant women because of the risks associated with malformation of teeth and bones in the developing fetus. Chloramphenicol has been used successfully to treat women with RMSF in the third trimester of pregnancy.[82,83] Because chloramphenicol crosses the placenta, low maternal dosages are given if the drug is administered during labor to avoid grey baby syndrome in the neonate, and use of doxycycline may be warranted in pregnant patients experiencing life-threatening complications due to RMSF.[61] Clinical findings of invasive meningococcal infection can overlap findings of RMSF, and empiric treatment for both diseases may be necessary. In these situations an appropriate parenteral penicillin or cephalosporin with activity against *Neisseria meningitidis* should be administered in addition to doxycycline.[61]

Advanced stages of RMSF are characterized by septic shock and systemic injury to the microvasculature, resulting in increased capillary permeability to multiple organ systems. Severely ill patients can have hemodynamic instability, disseminated intravascular coagulation, oliguria, azotemia, and severe pulmonary and cerebral edema. Close hemodynamic and electrolyte monitoring, coupled with inotropic support and administration of intravenous fluids, is warranted in these patients; however, because of increased capillary permeability, fluid replacement should be provided cautiously to avoid increasing pulmonary or cerebral edema. The ability to restore blood volume adequately in these patients is ultimately dependent on vascular integrity, which further emphasizes the need to rapidly initiate appropriate antibiotic therapy when RMSF is considered as a potential cause of illness.

Longterm neurologic sequelae, including hearing loss, speech dysfunction, hypertonia, paresis, parethesias, bladder and bowel dysfunction, and vestibular and swallowing disorders, can occur in people who survive severe disease.[84] In a recent series of 93 children diagnosed with RMSF, 13 had neurologic deficits at hospital discharge.[37] In children, behavioral disturbances and learning disabilities are among the most frequently described sequelae and generally occur in patients in whom severe alterations in consciousness occurred during the acute illness.[37,85] Gangrene and extensive skin necrosis are relatively uncommon manifestations that occur in patients recovering from severe disease and may involve digits, hands, feet, ears, nose, scrotum, or entire limbs (Fig. 178.5); more than 50% of surviving patients with these manifestations require amputation or extensive debridement.[86,87]

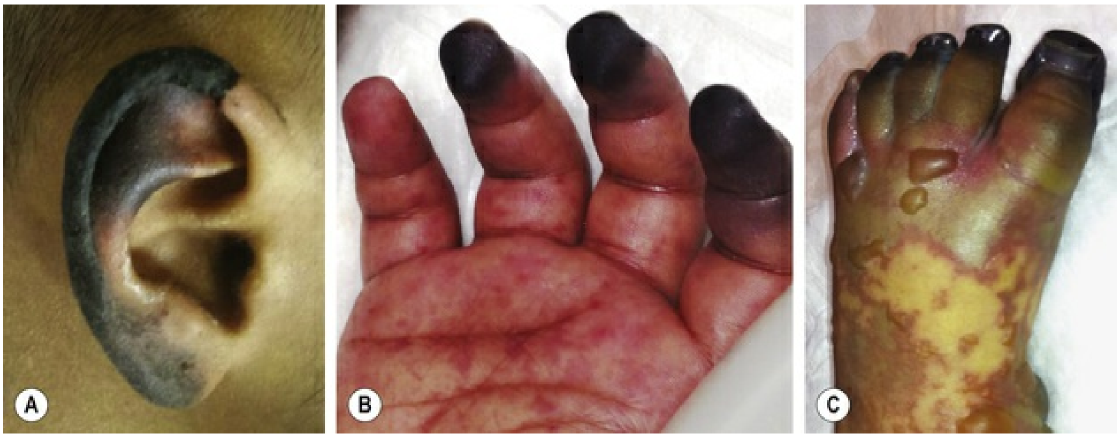

FIGURE 178.5 Gangrene involving the external ear (A), hand (B), and foot (C) of children with severe Rocky Mountain spotted fever.

Prevention and Control

Because RMSF can be difficult to diagnose clinically and requires specialized laboratory methods to confirm a suspected diagnosis, many cases likely are missed, misdiagnosed, or underreported. Confirmed cases should be reported promptly to state public health authorities. Accurate and timely reporting is essential for assessing the magnitude and distribution of cases of RMSF to develop effective public health education programs and prevention strategies.

There is no commercially available vaccine to prevent RMSF. Limiting exposure to ticks is the most effective way of reducing the likelihood of acquiring RMSF and depends primarily on avoidance of tick-infested sites. Because several important tick vectors of *R. rickettsii* are closely associated with dogs, treatment of family pets with appropriate tick preventives, including collars, sprays, or topical medications, is an important method to reduce ticks in the peridomestic settings.[88,89] Although dogs do not pose a direct communicable disease risk to humans, they can transport infected ticks into or around homes of the pet owner and represent important sentinels for human risk.[90,91] In recent outbreaks in the southwestern US and northwestern Mexico, many patients lived in poverty and in close association with large numbers of tick-infested, free-roaming dogs.[16,43] In these settings, socioeconomic and environmental conditions can contribute to epidemic levels of disease, particularly in vulnerable populations with limited resources to guarantee pet care.[92]

When engaging in outdoor activities, especially during spring and summer months, topical application of 30% *N*,*N*-diethyl-*m*-toluamide (DEET) is recommended as an acaricide repellent for use on children older than 2 months.[93,94] Additional personal protective measures include wearing light-colored clothing to help visualize crawling ticks and use of permethrin-impregnated clothing.[95] Parents whose children are frequently exposed to tick-infested habitats should employ daily tick checks, removing ticks as soon as possible to reduce the chance of disease transmission. Ticks can attach to concealed areas, including the scalp, axilla, and perineum, so careful searches are necessary. Expeditious removal of attached ticks reduces the chance of acquiring the disease after a tick bite because disease transmission may require several hours of attachment. To remove an attached tick, blunt curved forceps or tweezers should be used to grasp the tick as close to the skin surface as possible then pull upward with steady, even pressure. The person removing the tick should wear disposable gloves and avoid crushing the body of the tick. Irritating the attached tick with petroleum jelly, gasoline, finger nail polish, hot matches, or isopropyl alcohol is ineffective and should never be done.[96,97]

Key Points

Diagnosis and Management of Rocky Mountain Spotted Fever

Microbiology

- Caused by *Rickettsia rickettsii*
- Small, obligately intracellular, gram-negative rod
- Targets mammalian endothelial cells
- Requires cell culture for isolation

Epidemiology

- Tickborne pathogen that is endemic throughout much of the Western Hemisphere

- Majority of US cases reported from Arkansas, Missouri, North Carolina, Oklahoma, and Tennessee
- Most US cases documented during April through September
- Case-fatality rates highest in children younger than 10 years
- Most cases occur sporadically, although family and community clusters are reported occasionally.

Diagnosis

- Clinical diagnosis of early disease is difficult; epidemiologic clues and awareness of pathogen endemicity are crucial to establishing an early diagnosis.
- Diagnosis can be confirmed by serology, molecular methods, immunohistochemistry, or cell culture isolation.
- The indirect immunofluorescence antibody assay is the reference standard for serologic diagnosis; however, diagnostic levels of antibody are absent in approximately 50% of patients during the first week of disease.
- Molecular detection of the pathogen in whole blood generally is insensitive during the early stages of infection.

Treatment

- Tetracycline-class antibiotics are the most effective antibiotics; doxycycline is the preferred drug for children of any age.
- For children weighing less than 45 kg, administer doxycycline at a dose of 2.2 mg/kg every 12 hours for 7 to 10 days, to be continued for at least 3 days after unequivocal evidence of clinical improvement.
- For children weighing 45 kg or greater, administer doxycycline at a dose of 100 mg every 12 hours for 7 to 10 days, to be continued for at least 3 days after unequivocal evidence of clinical improvement.

Other *Rickettsia* Species

Marina E. Eremeeva, Gregory A. Dasch

Rickettsia prowazekii (Classic Louse-Borne Epidemic Typhus; Brill-Zinsser Disease or Recrudescent Typhus; Sylvatic or Flying Squirrel–Associated Typhus)

Description of Pathogen

Rickettsia prowazekii is a small, gram-negative, obligately intracellular, rod-shaped bacterium.[1,2] *R. prowazekii* possesses a surface autotransporter protein (OmpB) layer external to the cell envelope that has a peptidoglycan sacculus located between the inner cytoplasmic and outer membranes. It does not possess flagella. Both humoral and cellular immune responses are directed against the surface layer protein and result in protective immunity that is dependent on methylation of lysine residues in this protein.[3,4] *R. prowazekii* grows freely in the cytoplasm of infected host cells and preferentially infects endothelial cells in humans.[5] *R. prowazekii* is the prototype species of the typhus group (TG), which is differentiated from the more diverse and numerous rickettsial agents in the spotted fever group (SFG) by its lipopolysaccharide

(LPS) group antigen and some biologic characteristics. Unlike SFG rickettsiae, which can survive and replicate for several days after death of their host cells, TG rickettsiae rapidly die after killing their host cells. However, *R. prowazekii* can retain high aerosol infectivity and viability in dried louse feces.[6] Similarly, it remains highly infectious after drying in media with high osmolarity and has been weaponized so that it could be used as an agent of bioterrorism. Consequently, *R. prowazekii* is a “select agent,” possession and distribution of which is tightly regulated in the United States and other countries.[7] Genetic variants of *R. prowazekii* with different geographic distributions are known.[8]

Epidemiology

Classic epidemic typhus is spread from infected to uninfected people by migration of the human body louse (*Pediculus humanus corporis*).[6,8,9] Infected lice defecate during feeding and excrete copious amounts of rickettsiae in their feces. Transmission occurs to nonimmune humans when louse fecal material or crushed lice are inoculated into the bite site or skin abrasions or conjunctiva (more rarely), or when they are inhaled. The lice die from the rickettsial infection within 2 weeks, but desiccated dead lice and fecal materials may remain infectious for much longer. Epidemic typhus is one of the classic plagues of humankind, having infected and killed millions of people in the preantibiotic era during epidemics until the middle of the 20th century.[10,11] However, major outbreaks still occur infrequently in sub-Saharan Africa, and sporadic cases continue to be reported from North Africa, Ethiopia, Peru, Russia, and the US.[12] Body lice live in clothing; classic epidemic typhus occurs typically in conditions where poverty, famine, and war, frequently accompanied by cold weather, lead to unhygienic conditions favoring louse infestation. Head and pubic lice have not been shown to be significant human vectors for epidemic typhus, although head lice can be infected with *R. prowazekii* and are closely related to body lice.[13,14]

Humans are the primary reservoir for *R. prowazekii*, in whom organisms persist despite strong humoral and cellular immune responses. Formerly infected people can suffer a relapse of typhus, known as *Brill-Zinsser disease* or *recrudescent typhus*.[15,16] The precise factors causing relapses are not well understood, but recrudescence of disease is thought to constitute the source of *R. prowazekii* that permits initiation of new outbreaks of louse-transmitted typhus. Because infestation with body lice is now uncommon in much of the world and fewer people who experienced primary epidemic typhus now exist in the population, both primary epidemic typhus and herd immunity have declined throughout the world since the 1970s. Indigenous louse-borne epidemic typhus has not occurred in the US since 1922, but Brill-Zinsser disease occasionally is seen among immigrants from historically endemic foci of epidemic typhus or people infected in concentration camps. Healthcare personnel and military personnel may be at particular risk for infection. The last major Burundi outbreak was first detected because of the fatal infection of an evacuated Swiss Red Cross worker.[17]

In 1975, Bozeman and colleagues first reported a sylvatic cycle of *R. prowazekii* in southern flying squirrels (*Glaucomys volans*) in Florida and Virginia, but it is likely that this reservoir extends through much of the range of this squirrel in the eastern US.[18] *R. prowazekii* can be transmitted experimentally between flying squirrels by squirrel lice *(Neohaematopinus sciuropteri)* and their fleas *(Orchopeas howardi)*. About 40 cases of human sylvatic typhus infections, including several in children, have been reported in the eastern US.[19,20] Cases usually occur during the winter months when squirrels may enter houses; many such patients report contact with flying squirrels or their nests and associated ectoparasites. The mechanism by which disease is transmitted to humans is unclear, and although squirrel fleas occasionally bite humans, it is more likely that aerosolized infected ectoparasite feces are the primary source of infection. The genetic types of *R. prowazekii* from flying squirrels differ from European and African types.[8,21]

R. prowazekii has been detected in *Hyalomma* ticks in Ethiopia and *Amblyomma* ticks from Mexico.[22,23] If confirmed, this unusual source may account for sporadic cases of primary epidemic typhus that are not associated with human body lice, infected flying squirrels, or recrudescent typhus.[12]

Clinical Manifestations

Epidemic typhus is fatal in 10% to 50% of untreated patients and is more likely to be clinically severe or fatal in people with concurrent malnourishment or other disease.[11,24,25] Onset of epidemic typhus is abrupt and occurs 7 to 14 days after exposure, whereas Brill-Zinsser disease can occur >40 years after primary infection. Patients manifest high prostrating fever with severe headache, limb pains, and vomiting. The patient often appears vacant and semi-mute and can have epistaxis and a dry cough. The classical macular or maculopapular, sometimes petechial, rash appears 5 to 7 days after onset of symptoms; later it becomes purpuric. The exanthem, which may be difficult to see on dark skin, begins on the trunk and spreads to the arms and legs but rarely involves the palms, soles, or face. Constipation is common, and paralytic ileus can occur. Typhus infrequently induces diarrhea or splenomegaly, which helps in its differentiation from typhoid and malaria, respectively. A cough and pneumonia is observed in two thirds of patients and nervous system involvement (drowsiness, disorientation, and delirium) is frequent. In severe cases, a meningoencephalitic syndrome occurs with meningismus, tinnitus, and hyperacusis, followed by deafness, dysphoria, agitation, and coma. Thrombocytopenia, jaundice, and abnormal liver function can occur in severe cases. Survivors can experience hemiparesis, acute transverse myelitis, or peripheral neuropathy. Complications include secondary bacterial infections, myocarditis, and peripheral gangrene or venous thromboembolism. Convalescence is rapid and uneventful if appropriate antibiotic therapy is initiated early after onset of disease. Classic epidemic typhus in pediatric patients often is a milder illness and has a lower fatality rate compared with adults and elderly people. Intoxication syndrome and cardiovascular and neurologic symptoms usually are less pronounced. Observations from the preantibiotic era indicate that epidemic typhus in pregnant women clinically resembles Brill-Zinsser disease with a good prognosis and low mortality; however, spontaneous abortion and premature birth can occur in 20% to 50% of pregnant patients.

In contrast to primary epidemic typhus, delirium is rarely noted in recrudescent typhus. Although Brill-Zinsser disease often is considered to be milder than primary disease, exceptions occur. Late in the second week of illness, fever and headache subside abruptly, and patients feel generally well. The clinical presentation of flying squirrel–associated typhus fever also appears to be milder than that observed in louse-borne epidemic typhus. Whether this difference in clinical presentation is related to the different strains associated with sylvatic *R. prowazekii* or to the relatively good nutrition, health, and supportive care in US cases is unknown.[18–20]

Clinical diagnosis of epidemic typhus can be difficult because of its resemblance to influenza, typhoid, meningococcal meningitis, hemorrhagic fevers, infectious mononucleosis, sepsis, measles, and malaria.

Laboratory Findings and Diagnosis

The white blood cell count frequently is reduced with a relative lymphocytosis during the first week of epidemic typhus, and can be elevated as disease progresses.[24] Eosinophils are decreased or absent during the entire febrile period. Anemia and increased erythrocyte sedimentation rate frequently are detected but return to normal after treatment. Nephritis occurs with azotemia and moderate amounts of albumin and granular casts in urine.

Diagnosis of epidemic typhus generally is suspected because of specific epidemiologic circumstances and clinical findings. Diagnosis of acute epidemic typhus can be made by polymerase chain reaction (PCR) assays for rickettsial DNA extracted from whole blood or the buffy coat fraction, or biopsies of the rash; PCR is sensitive and specific.[26,27] Detection of rickettsial DNA in squirrel tissues and ectoparasites provides alternative detection of the etiologic agent.[18,28] Immunohistochemical procedures also can be applied to biopsy and ectoparasite samples. However, these procedures are available only in specialty laboratories, and prompt submission and correct handling of samples is essential for agent detection. Isolation is possible from acute phase blood and biopsy samples collected before initiation of antimicrobial therapy, in laboratories with access to embryonated chicken eggs, susceptible animals, or antibiotic-free cell cultures.[29] Isolation can require up to several weeks. Isolates of *R. prowazekii* are differentiated readily from other species of *Rickettsia* by genetic, biologic, and antigenic criteria.

The indirect immunofluorescence assay (IFA) is the current gold standard for serologic diagnosis of epidemic typhus.[30–32] Diagnosis is based on a fourfold rise in immunoglobulin G (IgG) antibody titers between acute and convalescent paired sera to *R. prowazekii* antigen or a high single titer of antibody with compatible clinical symptoms. Other serologic procedures for the specific detection of TG antibodies include enzyme immunoassay (EIA), complement fixation, latex agglutination, dipsticks, and chromatographic flow assays. Commercial testing usually employs IFA or EIA methods. The nonspecific Weil-Felix febrile agglutination test, which detects IgM antibodies to a typhus cross-reactive LPS epitope found in *Proteus* OX19 antigen, is not used in the US but is sometimes employed in less developed countries. Serologic cross-reactions can occur between TG and SFG of *Rickettsia,* and IgM antibodies can react with some *Legionella* and *Proteus* spp.[31] Cross-absorption of sera for IFA testing or Western blotting analysis differentiates epidemic and murine typhus and excludes other cross-reactions.[32]

Treatment

Treatment must be instituted before the diagnosis of epidemic typhus is confirmed by laboratory testing. Tetracyclines and chloramphenicol are effective against all forms of typhus infections, whereas ciprofloxacin and azithromycin have failed in the treatment of primary disease and Brill-Zinsser disease, respectively.[15,33,34] Doxycycline is the preferred treatment for both adults and children of all ages.[35,36] Dosage is 4 mg/kg/day (maximal dose, 200 mg/day), given orally or intravenously divided into doses every 12 hours, for 7 to 10 days. A single dose of 200 mg of doxycycline orally for adults and 100 mg for children is efficient in the control of epidemics where continuous patient management can be difficult. Chloramphenicol (50 mg/kg/day divided into doses every 6 hours for children for 7 to 10 days) also is effective; however, the use of chloramphenicol has been associated with increased risk for fatal outcome and relapses in Rocky Mountain spotted fever and typhus.[37] Marked improvement with defervescence should be apparent within 48 hours after treatment, but other symptoms can persist for up to 1 week. Development of specific immune responses is important for full recovery because the antibiotics of choice are bacteriostatic, not bactericidal.

Prevention and Control

Sporadic cases of Brill-Zinsser disease can occur in the US, primarily among immigrants from areas endemic for epidemic typhus, but they pose little risk for spread except from individuals infested with body lice. Head lice have never been associated with outbreaks of epidemic typhus, but body lice continue to be present in many regions of the world and can serve as a source of epidemic typhus in areas that presently are free of lice. No licensed vaccine is available. Exclusion of flying squirrels and their nests from domiciles to prevent concomitant exposure to their ectoparasites, use of pyrethrin-containing insecticides, and decontamination of infested clothing by washing with detergent at high temperatures are recommended for prevention and control.

Rickettsia typhi (Murine Typhus; Endemic or Flea-Borne Typhus)

Description of Pathogen and Epidemiology

Rickettsia typhi is a member of the TG of rickettsiae and closely resembles the other member of that group, *R. prowazekii*, in its genetic, biologic, and immunologic properties.[1,2,38,39] *R. typhi* replicates to higher titers in the yolk sacs of embryonated chicken eggs and is more infectious for laboratory mice and guinea pigs than *R. prowazekii*, but it is not regulated as a “select agent” in the US.

Commensal rats of the genus *Rattus* are the primary zoonotic reservoirs for *R. typhi*.[39] The oriental rat flea (*Xenopsylla cheopis*) is the classic vector that transmits murine typhus to humans but six genera and seven species of flea, including the cat flea (*Ctenocephalides felis*), have been found to be naturally infected with *R. typhi*.[39] Cats and peridomestic opossums infested with cat fleas have been implicated in the maintenance of *R. typhi* in the US; however, murine typhus from this source likely is rare.[40–42] Fleas are infected for life after feeding on *R. typhi*–infected rodents. The fleas shed organisms in their feces, and humans become infected through contact between flea feces and abraded skin, or possibly through inhalation of fecal material. Besides rats, fleas may be an important reservoir of *R. typhi* because they can transmit the organism transovarially to their progeny.[43]

Murine typhus has been diagnosed throughout the world but is reported most frequently from warmer climates and coastal areas where *Rattus* and fleas flourish.[44–50] Typically, seaports, coastal areas, and the major commercial arteries are disease-endemic sites. Only 333 cases of murine typhus were described in the US in 1931 and 2000 cases in 1933; however, by World War II, more than 5000 cases were documented annually in the US.[49,50] After World War II, flea and rodent control programs caused a precipitous drop in the number of reported cases. The current prevalence and distribution of murine typhus in the US are unclear; infection has been reported most commonly from focal areas in California, Texas, and Hawaii.[40–42,51,52] Both sporadic cases and small outbreaks can occur. Disease can be imported by travelers returning to the US from southern Europe, Asia, and Africa.[53,54] The disease occurs both in urban and rural settings, and travelers may be exposed by entering commercial areas and marketing districts infested with rats. The homeless appear to be exposed to this urban disease as well.[55] Based on the World Health Organization Reference Center in Marseille, France, half of the travel-associated cases of murine typhus were diagnosed in August and September, and most tourists were returning from Africa and Southeast Asia.[54]

Clinical Manifestations

Murine typhus manifests with fever, chills, headache, and myalgia. Although the disease generally is mild clinically, up to 10% of adults require intensive care with mortality approaching 4% for untreated cases. Most cases of murine typhus in the US occur in adults, but children are infected frequently in many parts of the world. A series of 96 serologically confirmed cases of murine typhus in children younger than 16 years from Texas provides the most complete clinical pediatric data available.[56] Fever occurred in all patients 8 to 16 days after exposure; headaches occurred in 76% with frontal distribution and dengue-like intensity. Rash occurred in 63% with a median onset at 6 days of illness, whereas the triad of rash, fever, and headache was found in only 49% of patients. Rash generally was macular (50%) or maculopapular (25%), and less frequently was erythematous, petechial, or papular. Although flea bites were reported in only 34% of patients, potential patient contact with animal reservoirs that likely were flea infested was found in 85% of the cases.

Nausea and vomiting occur during the early stage of illness in almost all infected adults. In contrast, children tolerate early disease symptoms well, with gastrointestinal tract symptoms (anorexia, vomiting, nausea, diarrhea, and abdominal pain) occurring in 27% to 46%, and pharyngitis, lymphadenopathy, and cough in 15% to 20%.[56] Pneumonitis, stupor, conjunctivitis, or photophobia occurred in only 5% to 12% of children. Splenomegaly and hepatomegaly were not common in this series, but these symptoms have been described previously in populations in the tropics.[57,58] Differences may be ascribed to early treatment of children in Texas or to coinfection with other common diseases in the tropics. Neurologic findings appear to be more common in adults (15%–45% in different studies) than children.

Most patients with murine typhus are hospitalized, and many patients have signs of sepsis and shock. Complications of murine typhus can include meningitis, meningoencephalitis, facial paralysis, hearing loss, ocular abnormalities, myocarditis, and renal and respiratory failure.[44–48,56–62] Severe hemolysis has been associated with glucose-6-phosphate dehydrogenase deficiency. Pediatric case reports of *R. typhi* have included parinaud oculoglandular syndrome, splenic rupture, myositis and paraparesis, and meningoencephalitis resulting in chronic cognitive impairment despite treatment.[63–66]

Laboratory Findings and Diagnosis

Laboratory findings are nonspecifically abnormal in murine typhus in children.[56] In the Texas case series, 81% had high erythrocyte sedimentation rate, 77% had a left shift in differential leukocyte count, 68% had absolute neutropenia, and 51% had absolute lymphopenia. Serum hepatic enzyme levels were measured infrequently but generally were abnormal. Serum electrolyte changes included hyponatremia (58%), hypokalemia (21%), and elevated serum creatinine (21%).

Although all patients in the pediatric case series were confirmed serologically by IFA, diagnostic titers were present in only 15% of patients at 7 days and 62% by 14 days after onset of illness. More than 28 days were required for all patients to exhibit diagnostic titers. Serologic tests for murine typhus use *R. typhi* antigen and detect cross-reactive antibodies that usually are elicited during both epidemic and murine typhus infections but less frequently in SFG infections.[30,32] With murine typhus, antibody titers to *R. typhi* may be higher than to *R. prowazekii*; antibody cross-absorption studies often are necessary to clearly distinguish murine and epidemic typhus.[32] Because circulation of *R. felis* also has been demonstrated in states traditionally endemic for murine typhus and *R. typhi* and *R. felis* share a number of cross-reactive antigens, differential serology of these flea-borne agents also may be necessary.[40–42,52,67–70] PCR tests that readily discriminate *R. typhi*, *R. prowazekii,* and *R. felis* are available.[68–70] Because fleas have high-density infections with *R. typhi*, PCR and immunologic detection of the agent in fleas are effective assays.[67–69,71]

Treatment and Prevention

Treatment regimens for suspected *R. typhi* infections are the same as those for *R. prowazekii* and other rickettsial infections.[35,72–74] Relapses have been reported in patients treated with chloramphenicol, but not those treated with tetracyclines, indicating that tetracycline or tetracycline analogs are preferable.[73] Ciprofloxacin also has been used successfully for treating adults with murine typhus. In a cohort of 87 adult patients from Greece, doxycycline treatment led to defervescence in 2.9 days (median), chloramphenicol in 4 days, and ciprofloxacin in 4.2 days.[74] Treatment regimens combining doxycycline with chloramphenicol or ciprofloxacin did not improve the clinical effectiveness of doxycycline. In children, median time to defervescence was 2 days for tetracycline and 2.5 days for chloramphenicol.[56,58]

No vaccine is available. Avoidance or elimination of rodent-infested areas are the best methods for preventing infection.[39] Rodent and flea eradication programs are recommended for areas where harborages already exist. Essential measures include rat proofing of homes and buildings, elimination of crowded and unsanitary housing conditions, and elimination or reduction of agricultural food sources and rat harborages in the domestic environment. Workers trapping and removing rats or working in rat harborages can use aerosol sprays of pyrethroid insecticides and protective clothing and masks to reduce risk for infection from fleas seeking new hosts and from residual flea feces. Control of opossums and their fleas has not yet been shown to be a necessary or effective strategy for murine typhus.

Rickettsia felis (Cat Flea Rickettsiosis) and Related Agents

Description of Pathogen and Epidemiology

Rickettsia felis was first recognized as a new rickettsial agent in 1992, shortly after its discovery by electron microscopy in the midgut epithelium and ovaries of the cat flea (*Ctenocephalides felis*), where it is maintained by transovarial passage.[75] *R. felis* can be isolated and grown in a variety of cells but is generally grown in arthropod cell cultures at 28°C. By comparative genomic analysis, *R. felis* appeared to be related most closely to *R. akari* and *R. australis*.[76] However, a group of new "*R. felis*–like" agents (e.g., *R. asemboensis* and *R. senegalensis*) have been discovered in a wide variety of arthropods, including ticks, mosquitoes, and tsetse flies since the mid-2000s.[77–80] The pathogenicity and antigenic characteristics of many of these related agents remains to be determined.[81–86] As with *R. akari,* the LPS of *R. felis* differs from that of prototypical SFG rickettsiae (i.e., *R. rickettsii* and *R. conorii*). Like other rickettsiae, *R. felis* has large surface layer protein antigens (Sca proteins) that are important targets in immune responses, but little is known about their biologic properties.[87–89]

R. felis has a worldwide distribution in association with many flea species and animal hosts.[40,51,52,68,70,75,81–84,90,91] Cat fleas infected with *R. felis* have been collected in many US states. The fleas are not affected by the presence of *R. felis* despite their location in midgut epithelial linings, tracheal matrix, muscle, ovaries, and epithelial sheath of the testes. *R. felis*–infected cat fleas can acquire *R. typhi* during a blood meal and maintain *R. typhi* for up to 9 days; however, effects of coinfection on the subsequent transovarial transmission of each agent were not determined.[69] *R. felis* also can coinfect fleas harboring *Bartonella quintana, B. henselae,* and *Wolbachia pipientis*.[92]

The capacity of vertebrate hosts to be infected or act as reservoirs for *R. felis* is not fully understood. *R. felis* DNA has been detected by PCR in opossums.[91,93] Up to 11% of US cats are seropositive for *R. felis*.[94] However, cats, rarely have detectable *R. felis* DNA, so it is likely that infected cat fleas are the main source of infections.[95]

Given the commonplace presence of *R. felis* in fleas in the domestic and peridomestic environments, it is surprising that so few PCR confirmed cases of infection with *R. felis* have been identified worldwide and that only one molecularly confirmed case has been reported in the US.[74–77,82,96,97] Of 32 human serum samples from Texas that were positive for antirickettsial antibodies, only three were positive for *R. felis* while the others reacted to *R. typhi* antigen; however, *R. felis* was more common than *R. typhi* in fleas and opossums.[97] Low case numbers may be due to lack of laboratories that are able to identify *R. felis,* lack of diagnostic testing in patients with mild influenza-like symptoms, low human susceptibility, or low pathogenicity of this agent. Serologic and molecular evidence for human infection with *R. felis* has been reported for patients from at least 18 countries around the world, including a travel case.[82,98]

Clinical Manifestations

An increasing number of human cases of *R. felis* infection with reliable laboratory support have been described, but the diagnostic criteria vary widely, and the specific agents involved may not all be the same. Confirmation by serology is the least certain. Clinical presentations of *R. felis* illnesses diagnosed in different countries vary. The *R. felis* case from Texas initially was diagnosed as murine typhus because the patient presented with a fever and headache and no apparent rash.[96] Two French cases were first diagnosed clinically as murine typhus or Mediterranean spotted fever.[81] Five patients treated in Mexico and Brazil had rash and systemic symptoms, including fever, headache, and myalgia; four had visceral involvement with abdominal pain, nausea, vomiting, and diarrhea; and four had involvement of the central nervous system (photophobia in two patients, hearing loss and signs of meningismus in one patient, and coma in one patient).[99] Some Mexican cases in the Yucatan had dengue-like illness, and others presented with pulmonary symptoms, a skin lesion consistent with an ulcer, or peripheral erythema.[100] Complications of *R. felis* infection in humans include hepatitis, polynephropathy, subacute meningitis, and splenic infarction.[100–104] A syndrome of vesicular fever called "yaaf" has been described in cases from Senegal.[105] The presence of *R. felis* DNA in fecal samples has been reported in Africa, but this is atypical for rickettsioses.[106] Seroprevalence to *R. felis* appears to be the same in healthy and HIV-infected individuals surveyed in Spain.[101] Recent reports from Africa suggested a correlation between geographic distribution, seasonality, asymptomatic infections, mosquito vectors for malaria, and the occurrence of *R. felis* infection.[107] Although there is conceivable concern that doxycycline prophylaxis for malaria in travelers may cause treatment failures or delayed onset of *R. felis* infections, the overall prevalence of *R. felis* infection in cases of undifferentiated fevers appears to be quite low.[82,108–110]

Laboratory Findings and Diagnosis

Patients with *R. felis* infection can have thrombocytopenia and increased levels of serum aspartate transaminase; anemia, leukocytosis, thrombocytosis, and prolonged prothrombin time; or leukopenia.[81]

Most cases lack detectable antibodies to rickettsiae in acute serum samples. Convalescent sera contain high antibody titers to *R. felis* (IFA IgG ≥512 and IgM titers of ≥64). Because *R. felis* shares antigens with typhus and SFG rickettsiae, cross-absorption of sera is necessary for specific diagnosis.[111]

Definitive diagnosis requires detection of *R. felis* DNA by PCR amplification.[74,76,77,80,81,99–103,108] PCR amplification and sequencing of *R. felis* DNA from skin biopsy, whole blood, and serum samples is done with primers for the *Rickettsia* 17-kd protein gene, 120-kd protein gene *(sca4), ompA, ompB,* and *R. felis* plasmid genes. A quantitative PCR assay that can differentiate *R. felis* from *R. felis*-like agents also has been described.[112]

No isolates have been obtained directly from patients. Conditions for optimal detection of *R. felis* in shell vial cultures have been evaluated, and *R. asemboensis* has been isolated in cell culture.[113,114] Although such methods have improved the rate of isolation of *R. felis* and *R. felis*–like agents present in high density in invertebrates, tests have been difficult to apply to clinical samples with typical low rickettsial density.

Treatment and Prevention

R. felis infections are treated with doxycycline. Chloramphenicol is an alternative when doxycycline is not available.[100] In vitro quantitative PCR data indicate that *R. felis* is susceptible to doxycycline (minimal inhibitory concentration [MIC], 0.06–0.125 μg/mL), rifampin (MIC, 0.06–0.25 μg/mL), thiamphenicol (MIC, 1–2 μg/mL), and fluoroquinolones (MIC, 0.5–1 μg/mL). Gentamicin, erythromycin, amoxicillin, and trimethoprim-sulfamethoxazole are not suitable therapies.[115]

R. felis appears to be maintained primarily in cat fleas infesting opossums in Texas and southern California. Rodents and other fleas may be more important hosts in other parts of the world. Cat fleas are promiscuous feeders on free-ranging wild and domestic cats and dogs and their owners. Elimination of open food sources like garbage, trapping and removal of opossums, and flea control of domestic animals are recommended for prevention of cat flea rickettsiosis.[116]

Rickettsia akari (Rickettsialpox)

Description of Pathogen and Epidemiology

Until the discoveries of *R. felis* and many other *Rickettsia* spp. associated with other arthropods, *R. akari* was considered the most unusual species of *Rickettsia* because it is transmitted by mites rather than ticks.[117–119] The SFG LPS of *R. akari* is unusual because it does not elicit typical OX2 and OX19 Weil-Felix agglutinin responses in humans like other SFG rickettsiae. Its surface protein antigens are important in protective immune responses and permit serologic discrimination from other SFG rickettsiae by IFA and Western blotting assays.[120] Inbred strains of mice differ in resistance to intraperitoneal challenge with different isolates of *R. akari*. Molecular differences between US and Ukrainian isolates also have been detected.

R. akari appears to be distributed widely in the world, but its natural history is incompletely understood. In the US, *R. akari* is best known for causing focal urban outbreaks of rickettsialpox after the bite of the house mouse mite (*Liponyssoides sanguineus*). After rickettsialpox was first identified in New York City in 1946, cases were reported from many other US cities.[118] However, of the more than 800 cases reported in the US, 500 were reported within the first 3 years after discovery, most in New York City. By the 1960s, a sharp decline occurred in reported cases of rickettsialpox, but it was unclear whether this was due to a change in incidence or recognition; increased alertness for eschar lesions after the anthrax investigation in New York City in 2001 led to the identification of rickettsialpox cases.[121–123] Human cases of rickettsialpox also have been reported from the former Yugoslavia, Northern Europe, Turkey, and Mexico.[124–127] A major outbreak in Ukraine occurred during 1949–1952, but no subsequent cases were reported there after elimination of the endemic foci.[119]

L. sanguineus is the major reservoir of *R. akari* because it maintains the agent by both transstadial and transovarial passage. Isolates also have been obtained from infected house mice and other rodents, and they can transmit *R. akari* to uninfected mites. *R. akari* has been isolated from commensal rats in the Ukraine and from voles in Korea.[128,129] However, the importance of rodents as reservoirs of *R. akari* in nature is unclear. *L. sanguineus* is a parasite of house mice *(Mus musculus)* and rats *(Rattus norvegicus* and *R. rattus)*, but voles and gerbils can be infected in the laboratory. Rodents and humans from California and dogs in New York City have been shown to have antibodies to *R. akari,* and *R. akari* was detected in *Rhipicephalus sanguineus* collected from a sick dog in Mexico.[130–132]

The mite abandons the host after feeding and can be found in mouse bedding and walls of infested rooms. Rickettsialpox appears to occur primarily when mice and rats are not available as the primary vertebrate hosts when the mites feed on humans as an available alternative host.[133] The decline in rickettsialpox in the inner city may be due to replacement of *L. sanguineus* with the tropical rat mite *(Ornithonyssus bacoti),* which can maintain *R. akari* by transovarial passage but is an inefficient vector of rickettsialpox.[134]

Clinical Manifestations

Rickettsialpox is a relatively mild illness and is rarely fatal, although more severe cases have been reported from Mexico.[126,132] Rickettsialpox affects males and females equally and has no age dependence. Three features are characteristic of the disease. First, after an incubation period of 7 to 14 days after the bite of the mite, the skin inoculation site has a firm red papule 1 to 1.5 cm in diameter. Shortly thereafter, the painless lesion vesiculates and becomes filled with cloudy fluid. As the lesion dries, it leaves a brown to black crust surrounded by a 0.5- to 3-cm area of induration. The initial lesion can be located anywhere on covered areas of the body; having more than one lesion is rare. Regional draining lymph nodes often are swollen, but lymphangitis has not been reported. In the second stage, an influenza-like syndrome begins abruptly about 1 week after exposure (up to 17 days later) with chills, fever, sweats, and myalgia. The peak temperature usually is 39°C to 40°C; without treatment, fever persists for about 7 to 11 days. Other common symptoms include profuse diaphoresis, headache (usually frontal), and photophobia; occasionally vertigo, rhinorrhea, cough, sore throat, nausea, vomiting, and constipation are present. Finally, usually within 1 to 3 days after the onset of constitutional symptoms, an exanthem appears as a single crop, with 5 to 100 discrete, firm erythematous papules on the face, trunk, and extremities; lesions are 2 to 10 mm in diameter and can develop a small vesicle or pustule in the center. Lesions can involve the palate, tongue, and pharynx, and less frequently (<10%) the palms or soles. In about 1 week, vesicles dry and form scales that do not scar but can result in postinflammatory hyperpigmentation. Untreated rickettsialpox usually resolves uneventfully in 2 to 3 weeks. Rickettsialpox most often is confused with chickenpox, but chickenpox lacks a primary eschar, and the vesicles rest on an erythematous base. The appearance of the eschar in rickettsialpox resembles the skin lesion developed in patients with cutaneous anthrax.[122,123]

Laboratory Findings and Diagnosis

Leukopenia (2400–4000 cells/mm^3) with relative lymphocytosis usually is detected during the early febrile stage of rickettsialpox. Hematocrit, hemoglobin, erythrocyte sedimentation rate, and electrolyte and serum transaminase values are normal; urinalysis can show mild proteinuria.[119,121,122]

Specific diagnosis typically requires a combination of clinical and epidemiologic findings in conjunction with group-specific serologic tests. Patients with a compatible illness and known or possible mite exposure should be tested for antibodies to SFG rickettsiae. *R. rickettsii* typically is used as a surrogate antigen because it is antigenically related to *R. akari* and is more widely available. Seroconversion in a clinically compatible case provides good evidence of rickettsialpox, but definitive evidence requires cross-absorption with SFG rickettsial antigens.[135] IFA tests or immunohistochemical staining of punch biopsies taken from skin lesions also have been used to confirm the diagnosis of rickettsialpox, but use of a species-specific antibody is necessary to confirm *R. akari* infection.[120,122,123,136] PCR amplification of a rickettsial 17-kd protein gene fragment or OmpB gene fragment followed by DNA sequencing has good diagnostic efficiency.[120,126] *R. akari* can be isolated from skin biopsy samples, and a multiplex PCR assay has been developed to differentiate rickettsialpox in skin samples from other spotted fever rickettsioses that are common in the US.[120,137]

Treatment and Prevention

No fatalities have been reported for rickettsialpox. Uncontrolled studies show that treatment with tetracyclines hastens defervescence and abatement of systemic symptoms within 48 hours. Dosage is the same as for other rickettsial infections; duration generally is 3 days after defervescence. Chloramphenicol is an alternative treatment when doxycycline is not available.[126]

No vaccine has been developed. Disease can be prevented by enforcing sanitary measures that preclude development of urban rodent harborages and their ectoparasites. Rodent eradication programs can eliminate infestation problems, but insecticides and acaricides must be applied simultaneously so that the ectoparasites do not seek alternative human hosts and initiate an outbreak.[116–118,133]

Rickettsia parkeri Rickettsiosis and Atlantic Rain Forest Rickettsiosis

Description of Pathogen and Epidemiology

Rickettsia parkeri, also called "maculatum agent," is a SFG rickettsia that was first recovered from the tick *Amblyomma maculatum* in the US in 1939.[138,139] Phylogenetically and microbiologically, *R. parkeri* clusters most closely in a genetic lineage together with *R. africae, R. sibirica,* and the unnamed isolate "S" obtained from *Rh. sanguineus* ticks in Armenia.[102a] Another genetic type (Atlantic Rain Forest) closely related to *R. parkeri* has been detected in *Amblyomma ovale* ticks from Colombia, Brazil, and Argentina.[140–144] Several cases of Atlantic Rain Forest rickettsioses have been described in Brazil, but *R. parkeri* infections are much more common and probably occur from the southern US to Argentina.[145–152]

The ecology and distribution of *R. parkeri* is not completely understood. In North America the Gulf Coast tick (*A. maculatum*) is the primary vector, and *R. parkeri* is transmitted transovarially and transstadially in these ticks.[152] *A. maculatum* is found in the US in southeastern and Gulf Coast states; inland populations also exist in Kansas and Oklahoma.[151,152] *A. maculatum* also is found in some countries of Central and South America and some Caribbean islands. *R. parkeri* also has been found in several other *Amblyomma* spp. ticks.[23,144,147–150] Human cases due to *R. parkeri* infection have been diagnosed in at least nine US states, Brazil, Uruguay, and Argentina.[150,153–155] Dogs develop *R. parkeri* rickettsiemia and may serve as a source of infected ticks to transmit infection to humans.[156]

The prevalence of *R. parkeri*–like agents in *Amblyomma* ticks is quite high compared with *R. rickettsii*, but acquisition or transmission may be limited by prior infection of ticks with *Rickettsia andeanae*.[157,158]

The Atlantic Rain Forest strain appears to be restricted to areas of tropical rain forest along the Atlantic Ocean and is most often detected in *Amblyomma ovale* but also has been found in *A. dubitatum*.[140–144] Other *R. parkeri*–like strains have been identified, but their reservoirs, vectors, and pathogenicity are unknown.[159–161]

Clinical Manifestations, Laboratory Findings, and Diagnosis

Patients infected with classical *R. parkeri* isolates in North and South America present with fever, headache, diffuse myalgia, and arthralgia. Single or multiple eschars are present in >90% of cases. An erythematous maculopapular rash develops on the trunk and spreads to the extremities, including the palms and soles. Some patients have a diffuse nonpruritic maculopapular and vesicular rash.

A mild leukopenia, elevated levels of serum hepatic enzymes, lactate dehydrogenase, and total bilirubin were detected in the blood of acutely ill patients. Paired acute and convalescent serum specimens show increases of IgG antibodies reactive with SFG rickettsiae. Because significant cross-reactivity exists among SFG rickettsiae, cross-absorption and Western blotting analyses are necessary to obtain specific serologic diagnoses, but these are insufficient for distinguishing among the isolates considered here. Histopathologic evaluation of biopsy specimens obtained from the rash or eschar reveal the presence of rickettsiae and lymphohistiocytic perivascular infiltrates. PCR amplification and sequencing of DNA from skin biopsy samples allow precise identification of the rickettsial etiologic agent.[137,150,154,162] Isolation in cell culture provides the best confirmation of the specific rickettsial etiology and permits further characterization of the biologic and immunologic properties of the organism.

Only two confirmed cases of Atlantic Rain Forest rickettsiosis have been reported, and their clinical differentiation from *R. parkeri* infection is not yet possible.[145,146] Both infections could be distinguished from Brazilian spotted fever by the presence of eschars and milder presentation.

Treatment, Prevention, and Control

Patients are treated with doxycycline as for other rickettsial diseases. Fever resolves within 24 to 48 hours, whereas malaise and rash have more gradual resolution. Laboratory test values return to normal within 1 month.

Prevention measures rely on reduction of exposure to ticks by avoiding tick habitat, reducing tick abundance in infested areas, wearing protective clothing, and checking for and removing ticks after exposure. Wearing long pants, long sleeves, and long socks will reduce tick attachment, but tucking pant legs into socks or boots and tucking shirts into pants is more effective. Light-colored clothing also can aid in spotting ticks more easily. Using insect repellent with 20% to 30% *N*,*N*-diethyl-*m*-toluamide (DEET) on skin and clothing to prevent tick attachment is recommended. Permethrin, another repellent that also kills ticks on contact, can be applied to clothing and gear.

Prophylactic antibiotic therapy is not recommended for people with attached ticks because it may only delay onset of disease and many ticks are not infected. People should remove attached ticks properly without crushing to avoid aerosolization and contamination of skin wounds.

Rickettsia philipii (Pacific Coast Tick Fever)

Description of Pathogen and Epidemiology

Rickettsia philipii is an SFG rickettsia that was first isolated from the Pacific Coast tick (*Dermacentor occidentalis*) in 1966; it can be distinguished by microimmunofluorescence typing from other SFG agents.[163,164] Its microbiologic characteristics are typical of other SFG rickettsiae. *R. philipii* is closely related to *R. rickettsii*, but it has less in vitro cytopathic effect. The first laboratory confirmed cases of *R.*

philipii were identified in adults in California in 2008; the first pediatric cases were reported in 2013.[165,166,166a]

D. occidentalis, the *R. philipii* vector, has a limited distribution spanning from Baja, Mexico to southern Oregon.[167] Approximately 7% of *D. occidentalis* in southern and northern California are infected with *R. philipii*, compared with <1% with *R. rickettsii*.[168] In northern California, adult *D. occidentalis* are most active March through May, whereas nymphal *D. occidentalis* are encountered more commonly during June through August, the peak times for occurrence of disease.[166a]

Clinical Manifestations, Laboratory Findings, and Diagnosis

R. philipii infection causes nonspecific clinical symptoms, including fever, fatigue, headache, and lymphadenitis or lymphadenopathy.[165,166,166a] The presence of a single, sometimes painful ulcerated eschar (or scab) on the neck, forearm, shoulder, neck, back, or eyebrow and lymphadenopathy associated with a previous tick bite at that site are significant diagnostic clues for clinical diagnosis. Rash is observed infrequently but may manifest as erythematous macules on the cheek and chest.[166] Most cases are mild and managed on an outpatient basis; however, cases requiring hospitalization have been reported.[166,166a]

Routine laboratory findings are not remarkable, although patients may exhibit elevated liver enzymes and C-reactive protein and low white blood cell counts.[166] Elevated antirickettsial IgG antibody titers can be detected after the second week after illness onset.[165] Etiologic diagnosis is made by PCR detection and sequencing *R. philipii* DNA present in skin punch biopsy samples collected from the eschar site.[165] If a skin biopsy is not indicated because of mild disease, collection of the eschar scab or a swab of the lesion might be sufficient for DNA detection.[166,166a,170]

Treatment, Control, and Prevention

Treatment is the same as for other rickettsial diseases and requires a full course of doxycycline. Pediatric patients of all ages are treated with 2 mg/kg/dose twice daily for 14 days and recover uneventfully; nearly complete resolution of the symptoms may be seen within 3 days.[36,166,171] Treatment with sulfa drugs may worsen the course of infection and prolong clinical symptoms and healing of skin lesions.[165]

Control and prevention of *R. philipii* infection is the same as for *R. parkeri*, discussed previously.

Orientia and Other *Rickettsia* Agents (African Tick Bite Fever and Other Travel-Associated Rickettsioses, Including Scrub Typhus)

Description of Pathogens and Epidemiology

The SFG rickettsiae comprise a large number of pathogenic agents with varied geographic distributions that are dependent on the presence of their different tick vectors (Table 179.1).[144,153,169,172–179] Recent studies suggest that 7% of bacterial illness in travelers returning from developing countries is due to rickettsioses.[176] *Rickettsia africae,* the agent of African tick bite fever, is the most common cause of rickettsial infection in travelers and is diagnosed in approximately 5% of European visitors to South Africa.[173] Based on serosurveys, the prevalence of infection in some populations in Africa may approach 55%, but the incidence of disease is less clear.[109,180]

TABLE 179.1

Differential Characteristics of Spotted Fever Rickettsioses Acquired Outside the United States

		Epidemiologic Features			
***Rickettsia* sp.**	**Disease**	**Arthropod Vector**	**Location**	**Season**	**Outbreaks**
R. aeschlimannii	Unnamed spotted fever rickettsiosis[a]	*Hyalomma marginatum marginatum, Hyalomma marginatum*	Southern Europe, northern Africa, South Africa	Year-round	Not reported

		rufipes, Rhipicephalus appendiculatus			
R. africae	African tick bite fever[a]	*Amblyomma hebraeum, Amblyomma variegatum*	Sub-Saharan Africa, West Indies	Year-round	Common
R. akari	Rickettsialpox	*Liponyssoides sanguineus*	Europe, Africa, Asia, Mexico	Year-round	Originally discovered as outbreaks, sporadic cases now
R. australis	Queensland tick typhus	*Ixodes holocyclus, Ixodes tasmanii*	Eastern Australia	June to November	None reported
R. conorii* subsp. *conorii	Mediterranean spotted fever	*Rhipicephalus sanguineus*	Southern Europe, Africa	Summer months	Sporadic cases
R. conorii* subsp. *caspia	Astrakhan spotted fever	*Rhipicephalus sanguineus, Rhipicephalus pumilio*	Volga delta of Russia, Kosovo, Chad	May through September	Sporadic cases
R. conorii* subsp. *israelensis	Israeli spotted fever[a]	*Rhipicephalus sanguineus*	Southern Europe from Portugal to Italy and Israel	Summer months	Sporadic cases
R. felis	Cat flea rickettsiosis	*Ctenocephalides felis*	Worldwide	Year-round	Sporadic cases
R. heilongjiangensis	Far Eastern spotted fever	*Dermacentor silvarum*	Far east of Russia, Northern China	Summer months	Sporadic cases
R. honei	Flinders Island spotted fever	*Aponomma hydrosauri, Ixodes granulatus*	Southeastern Australia, Thailand	December to January	Sporadic cases
R. honei* strain *marmionii	Flinders Island spotted fever	*Haemaphysalis novaeguineae*	Eastern seaboard of Australia	February to June	Sporadic cases
R. japonica	Oriental (Japanese) spotted fever	*Ixodes ovatus, Dermacentor taiwanensis, Haemaphysalis longicornis, Haemaphysalis flava*	Japan, Korea, Taiwan	April to October	Sporadic cases
R. kellyi	Unnamed rickettsiosis	Unknown	India subcontinent, Sri Lanka	Unknown	Sporadic cases
R. massiliae	Unnamed rickettsiosis	*Rhipicephalus sanguineus Rhipicephalus turanicus*	Mediterranean countries, Africa, South America	Spring and summer months	Sporadic cases
R. parkeri	Maculatum infection	*Amblyomma maculatum,*	Argentina, Bolivia, Brazil,	Spring to summer	Sporadic cases

		Amblyomma cajennense, *Amblyomma triste* *Amblyomma tigrinum* *Amblyomma nodosum*	Uruguay	months	
R. raoultii	Tickborne lymphadenopathy, *Dermacentor*-borne necrosis and lymphadenopathy	*Dermacentor marginatus* *Dermacentor reticulatus*	Europe to Asia	March–May to September–November	Sporadic cases
R. rickettsii	Rocky Mountain spotted fever, São Paulo exanthematic typhus, Minas Gerais exanthematic typhus, Brazilian spotted fever[a]	*Amblyomma cajennense* *Rhipicephalus sanguineus* *Amblyomma imitator*	Mexico, Costa Rica, Panama, Brazil, Argentina	Spring to fall months	Sporadic cases, also outbreaks and family cluster cases can occur
R. sibirica	Siberian tick typhus[a]	*Dermacentor nuttalli*, *Dermacentor marginatus*, *Dermacentor silvarum*, *Haemaphysalis concinna*	Europe, Asia	Spring to summer months	Sporadic cases
R. sibirica* subsp. *mongolotimonae	Lymphangitis-associated rickettsiosis	*Hyalomma asiaticum*, *Hyalomma reticulatus*	Southern France, Asia, Africa[b]	Late spring to early summer	Sporadic cases
R. slovaca	Tickborne lymphadenopathy, *Dermacentor*-borne necrosis and lymphadenopathy	*Dermacentor marginatus*, *Dermacentor reticulatus*	Europe, Asia	October through May	Sporadic cases
R. tarasevichiae	Unnamed spotted fever rickettsiosis[a]	*Ixodes persulcatus*	Arkhangelsk region of Russia to the Far East and to Northern China	Spring to fall months	Sporadic cases

[a] Indicates diseases reported for international travelers from endemic areas.

[b] Original isolation of a reference strain of *R. sibirica* subsp. *mongolotimonae* was made from *Hyalomma asiaticum* ticks from Northern China.[209–211]

[c] Prevalence has not been reported if numbers in parentheses are not shown.

[d] The case-fatality rate due to *R. rickettsii* infection depends on patient's age and time of initiation of antibiotic therapy.

R. africae is transmitted by *Amblyomma* ticks (e.g., *A. herbraeum* and *A. variegatum*) that are found on cattle and game in rural areas of tropical and subtropical sub-Saharan Africa.[173,177] *R. africae* also has been detected in *Rhipicephalus* spp. ticks, but their role in transmission is unknown. Although most cases of African tick bite fever occur in sub-Saharan Africa, *R. africae* also is found in ticks on Indian Ocean islands and in north Africa, the Middle East, parts of Europe, and the Caribbean.[181–191]

Other spotted fever group rickettsioses and their epidemiologic features are summarized in Table 179.1.[177,178] Boutonneuse fever (Mediterranean spotted fever) is caused by *R. conorii* subsp. *conorii,* which is distributed throughout Africa, southern Europe, and the Indian subcontinent.[192,193] *R. conorii* subsp. *caspia* and *R. conorii* subsp. *israelensis* have been described primarily in the Mediterranean-Caspian region, but distribution likely extends to the Indian subcontinent.[193,194] *Rickettsia massiliae* has been identified as a cause of rifampin-resistant rickettsiosis in Spain, Italy, France, and Argentina.[195–197] It has been detected in ticks in Arizona, California, and Maryland.[198–200] *Rickettsia honei* has been found in Southeast Asia, Nepal, and Australia.[172,177,201,202] *Rickettsia japonica* (Japanese spotted fever) and *Rickettsia tamurae* cause infections in Japan and Korea.[177,203,204] *Rickettsia heilongjiangensis* has been identified in patients in China, Russia, and Japan.[177,205,206] Siberian tick typhus, which is caused by *Rickettsia sibirica* sensu stricto, is transmitted by *Dermacentor* spp. ticks in a large area from Russia to India and China.[207,208] *Rickettsia sibirica* subsp. *mongolotimonae* causes infections in southern Europe, Africa, and Asia and can be diagnosed by eschar swab.[209–211] *Rickettsia aeschlimannii* and similar rickettsiae are implicated in human disease cases reported from Africa, southern Europe, and Central Asia.[177,212–214] *Rickettsia slovaca* and *Rickettsia raoultii* cause sporadic and atypical rickettsioses in Eurasia, and *Rickettsia helvetica* is found throughout the wide distribution of *Ixodes ricinus* ticks.[215–218]

Orientia tsutsugamushi, the etiologic agent of scrub typhus, is related to *Rickettsia* but differs in its cell wall structure, staining properties, and morphology; it lacks peptidoglycan and LPS and has a unique set of major surface antigens.[1] This antigenically diverse agent is transmitted by numerous species of trombiculid mites (chiggers) in the Asia-Pacific region from Australia to Russia and from New Guinea to Afghanistan and causes an estimated 1 million disease cases per year.[219,220] Other similar agents recently have been identified in the Middle East, Africa, Europe, and South America, but the clinical and public health implications of these findings are unknown.[221–223]

Clinical Manifestations

Differential clinical features of these rickettsioses are described in Table 179.1. A characteristic of many of these infections is the development of an eschar at the site of a tick or mite bite, either immediately before or coincident with the onset of constitutional symptoms.[120,146,161,165,166,170,197,211,215] Multiple eschars are common in African tick bite fever and *R. parkeri* rickettsiosis. Illness typically occurs 1 week after a tick bite and is characterized by the abrupt onset of fever, headache, lymphadenopathy, and malaise. With *R. conorii* and *R. australis* infection, a maculopapular rash usually appears between days 3 and 5 and typically affects the extremities first before spreading to include the trunk. *R. africae* infections may be less likely to cause a rash; they also are characterized by a delayed antibody response compared with Mediterranean spotted fever. Other symptoms include hepatomegaly, splenomegaly, conjunctivitis, and gastrointestinal tract manifestations. These agents usually cause mild to moderate disease, with occasional severe complications reported, including neuropathy and skin necrosis. However, case-fatality rates of up to 3% have been reported for *R. conorii* subsp. *conorii,* with similar rates for *R. australis, R. japonica,* and *R. honei*. Different inflammatory and immunologic responses underlying the pathogenesis of rickettsial infections are in part due to expression of homeostatic chemokines (CCL19, CCL27, and CCR7), proinflammatory cytokines (interleukin-8), and cell adhesion molecules.[224,225]

R. slovaca and *R. raoultii* cause tickborne lymphadenopathy or *Dermacentor*-borne necrosis and lymphadenopathy.[215,216] Patients have a large eschar on the scalp and enlargement of the cervical lymph nodes; only one third of patients develop fever. Peak incidence months are March through May and September through November, when *Dermacentor* ticks are most active. Patients infected with *R. helvetica* develop acute illness with rash, meningitis, or persistent myasthenia.[217,218] Most cases of scrub typhus have a heralding eschar. Scrub typhus can cause multiorgan involvement, pulmonary complications, meningoencephalitis, renal failure, jaundice, hepatitis, gastrointestinal tract dysfunction, and sepsis complicated by secondary bacterial, viral, fungal, or parasitic infections.[226–228]

Diagnosis

Diagnosis of these rickettsioses is most commonly made retrospectively by serologic testing.[229] Because specific tests are available only in specialty laboratories in the US, assays employing *R. rickettsii* are used as a surrogate cross-reactive antigen by commercial and state laboratories. Antigen-specific serologic tests for most of the SFG rickettsioses and scrub typhus are available on request from the Centers for Disease Control and Prevention. Confirmed infections exhibit a fourfold change in antibody titer between acute and convalescent serum specimens. A single high titer with a clinically compatible illness is considered a probable case. Acute phase samples, particularly whole blood and skin biopsy samples collected before antibiotic treatment, can be used for the direct identification of rickettsial DNA by PCR amplicon sequencing. Invasive punch biopsy procedures can be replaced by sampling the scab or a cutaneous swab collected before or within 24 hours after antibiotic therapy is initiated.[170,177,211] Rickettsial etiology also can be confirmed by immunohistochemistry tests performed on formalin-fixed paraffin-embedded tissues or direct cell culture isolation of rickettsiae from appropriately collected specimens and identification of the specific agent by PCR.[122,136,137,203]

Treatment and Prevention

Therapy is given empirically using drugs and dosage as for other rickettsioses. Doxycycline is the drug of choice for children of all ages and adults.[36,171] For patients in whom life-threatening reactions to doxycycline have been documented, intravenous chloramphenicol is an alternate antibiotic. Rifampin should be excluded as an antibiotic of choice if infection with *R. massiliae* or *R. aeschlimannii* is suspected because these rickettsiae are resistant to rifampin.[230] Cases of scrub typhus from northern Thailand responding poorly to doxycycline and chloramphenicol have been described in which 900 mg of daily rifampin was effective.[231,232] Azithromycin can be used for treatment of scrub typhus in patients for whom tetracyclines and chloramphenicol are not recommended.[233] Intravenous azithromycin has been shown to be as effective as intravenous doxycycline in the treatment of complicated scrub typhus.[234] Fluoroquinolones are ineffective in the treatment of scrub typhus because of intrinsic resistance of *Orientia*.[235,236]

Vaccines are not available. Prevention depends on avoiding arthropod bites and rodent- and ectoparasite-infested habitats. When traveling in these environments, people should wear long sleeves and pants, with the ends tucked into socks or sealed with tape. Use of permethrin-treated clothing may help repel ticks and mites. Repellents containing DEET can be applied to the skin. Adults should perform a body check on themselves and children daily after exposure to wild habitats and carefully and immediately remove any ticks and mites that are found to reduce the likelihood of transmission of rickettsiae.

Streptobacillus moniliformis (Rat-Bite Fever)

Lorry G. Rubin

Streptobacillus moniliformis and the recently described *S. hongkongensis*[1] are the only species in the genus *Streptobacillus.* They are fastidious, nonmotile, gram-negative, pleomorphic and often filamentous, beaded, facultative anaerobic bacilli. *S. moniliformis* can exist in two phases: the bacillary phase and the cell wall-deficient L-phase.[2,3] In addition to being the main etiologic agent of a systemic illness called *rat-bite fever, S. moniliformis* causes Haverhill fever. Sodoku (spirillary rat-bite fever), an extremely rare disease in the United States, is the name given to rat-bite fever caused by *Spirillum minus,* which manifests 1 to 4 weeks after a bite with relapsing fever, ulceration at the site of the bite, and associated regional lymphadenopathy. *S. minus* is a spiral gram-negative coiled bacillus with two or more helical turns and is motile. *S. minus* has not been isolated on solid media, and its diagnosis relies on visualization by darkfield microscopic examination of an ulcer or blood smear or on a Giemsa- or Wright-stained smear. This infection responds rapidly to therapy with penicillin.[3]

Epidemiology

The natural habitat of *S. moniliformis* is the upper respiratory tract of rodents, including wild or laboratory rats as well as mice, gerbils, and squirrels, where carriage is common and asymptomatic.[4] The organism can be excreted in rat urine. Humans are infected by the bite of a rat (or rarely mouse or squirrel) or, less commonly, from a scratch by a rat, from rat contact in the presence or absence of a break in the skin, from handling a dead animal, from skin injury from the cage of a rat,[5] or from contact with a rat-eating carnivore such as a dog, cat, or weasel.[2,3] In some cases a pet rat had died recently of an unknown illness.[6] Contact with pet rats account for most cases in some areas.[7] In some persons with no history of rodent contact, infection may have been acquired through ingestion of milk or water contaminated with rat excreta, as occurred in epidemic form in 1916 in Haverhill, Massachusetts, and in the 1980s in England.[8] Approximately 50% of cases of rat-bite fever are reported in children.

Clinical Findings

Two to 10 days (or up to 3 weeks) after a rat bite, there is an abrupt onset of fever accompanied by chills, headache, vomiting, myalgia, sore throat, and a rash that is maculopapular in appearance and frequently includes petechiae and at times pustules.[6] The rash is most prominent on the extremities and frequently involves the palms and soles. The bite wound usually has healed and exhibits no or minimal inflammation. Regional lymphadenopathy can occur in up to 25% of cases. Fifty percent of patients experience a migratory polyarthritis or polyarthralgia (erythema arthriticum epidemicum) typically involving the knees and ankles. Young children can have diarrhea and weight loss. Clinical features can be similar to Rocky Mountain spotted fever, septicemia due to *Neisseria meningitidis*, disseminated gonococcal infection, or secondary syphilis.

Untreated *S. moniliformis* infection usually follows a relapsing course for a mean of 3 weeks before spontaneous resolution. However, in untreated patients the mortality rate is approximately 10% and appears to be highest in young infants and those with endocarditis; cases of rapidly fatal infection have been reported.[2,3,7,9,10] Arthritis persisting for several months can occur.[3,10] Other reported manifestations are fever without a focus, endocarditis, myocarditis, meningitis, spinal epidural abscess, focal abscesses including brain and skin,[11] pyogenic arthritis typically with polyarticular involvement but without rash, or bacteremia,[12] pneumonia, hepatitis, nephritis, and amnionitis.[3,9,10]

When the infection is acquired through ingestion of the organism from water, milk, or food contaminated with rat excrements, it is known as *Haverhill fever*. Fever, chills, headache, pharyngitis, and vomiting are prominent and often are followed by rash and polyarthralgia or polyarthritis.

Diagnosis

The diagnosis is established by recovery of the organism from culture of blood, joint fluid, or abscess specimens in broth or on solid media. Identification often is established using polymerase chain reaction amplification of a segment of the 16S rRNA gene using specific primers. Media enriched with horse serum, sheep or rabbit blood, or ascites fluid and yeast extract and incubation in a 5% to 10% CO_2 atmosphere are required to recover *S. moniliformis*.[3,4] On solid media, small round grey colonies are noted within 3 days; in addition, mycoplasma-like colonies with a fried-egg appearance can develop. Isolation of the more fastidious L-phase variants requires an enrichment medium such as brain-heart infusion broth supplemented with horse serum and yeast extract. Sodium polyanethol sulfonate can inhibit *S. moniliformis*.[4,13] Although Bactec blood culture medium contains sodium polyanethol sulfonate, *S. moniliformis* has been recovered using Bactec Peds-Plus and Bactec Plus media,[11] perhaps because they contain resin. Growth in broth appears as "puffball" colonies at the bottom of the vial after 2 to 6 days. Occasionally, gram-negative pleomorphic bacilli are visualized on a smear of a clinical specimen such as a skin lesion, or bacilli are visualized on a blood smear.[9]

Alternatively, diagnosis can be established by polymerase chain reaction amplification of a segment of the 16S rRNA gene using broad-range primers followed by sequencing or electrospray ionization followed by mass spectrometry. Using this method, *S. bacilliformis* has been detected in clinical specimens such as joint fluid or post-mortem tissues as well as in incubated culture media.[4,5,14] At least 25% of patients infected with *S. moniliformis* have a false-positive reaction to the Venereal Disease Research Laboratories (VDRL) test for syphilis.[3]

Treatment

Penicillin is the drug of choice for treatment of persons with rat-bite fever, although penicillin-resistant strains have been reported rarely.[3] Isolates are susceptible in vitro to penicillin, ampicillin, cefuroxime, cefotaxime, clindamycin, tetracycline (doxycycline), streptomycin, and vancomycin. Doxycycline is an acceptable alternative agent to penicillin.[15] Failure of erythromycin treatment and successful treatment with clarithromycin have been described.[11,16] The L-phase of *S. moniliformis* is resistant to penicillin but responds to tetracycline.[2] For therapy of endocarditis caused by *S. moniliformis*, the addition of streptomycin to high dosages of penicillin should be considered.[3] Susceptibility to aminoglycosides and fluoroquinolones is variable. *S. moniliformis* is resistant to trimethoprim-sulfamethoxazole, nalidixic acid, and colistin[4] and sulfonamides are ineffective.[3]

Prevention

Avoiding contact with rodents and their excreta or wearing gloves for such contact is the best means of prevention. The rate of rat-bite fever after a rat bite is approximately 10%.[3] Individuals who sustain rat-bite wounds should be observed closely; penicillin prophylaxis can be considered.

Other Gram-Negative Coccobacilli

Lorry G. Rubin

A large number of gram-negative coccobacilli have been reported to cause infections in humans. This chapter describes four coccobacilli not discussed in other chapters. These organisms are important in specific epidemiologic and clinical settings and present special problems of diagnosis and therapy.

Aggregatibacter Species

Aggregatibacter (formerly *Actinobacillus*) *actinomycetemcomitans,*[1] a small, fastidious gram-negative coccobacillus, is a cause of endocarditis, of periodontal infection, and, in conjunction with *Actinomyces israelii,* of pneumonia and soft tissue abscesses (see Chapters 187 and 195). The other species of this newly formed genus are *Aggregatibacter* (formerly *Haemophilus*) *aphrophilus*, which can cause bone and joint infections, spondylodiscitis, brain abscess, and endocarditis; and *Aggregatibacter* (formerly *Haemophilus) paraphrophilus* and *Aggregatibacter* (formerly *Haemophilus*) *segnis,* both of which can cause endocarditis. The other *Actinobacillus* species—*A. equuli* subsp. *equuli, A. equuli* subsp. *haemolyticus, A. lignieresii, A. ureae,* and *A. hominis*—occasionally are associated with human disease; the first three primarily infect animals.

A. actinomycetemcomitans commonly is part of the normal flora of the mouth of humans, especially in gingival and supragingival crevices and also of various animal species.[2] The incidence of carriage is markedly higher in individuals with refractory periodontitis and in people with juvenile periodontal disease.[2] The organism can be transmitted among household members.[2]

A. actinomycetemcomitans contributes to the HACEK organisms, an acronym for a group of fastidious gram-negative coccobacilli that also include *Haemophilus parainfluenzae, Aggregatibacter* (formerly *Haemophilus*) *aphrophilus, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella kingae* that cause endocarditis. Poor dentition or recent dental manipulation is a risk factor for *A. actinomycetemcomitans* endocarditis, and most patients are adults with underlying valvular heart disease. Infection manifests subacutely with a mean interval from onset of symptoms to diagnosis of 3 months. Symptoms include fever, chills, malaise, anorexia, and weight loss.[3] Hepatosplenomegaly and peripheral stigmata, including petechiae, are common clinical findings. The incidence of embolic phenomena is similar to that in persons with endocarditis from other causes. Anemia and an elevated erythrocyte sedimentation rate are common laboratory findings.

The most common illness associated with *A. actinomycetemcomitans* is juvenile and adult periodontal disease. *A. actinomycetemcomitans* also causes soft tissue abscesses, particularly of the chest wall or mandibular area, often as a coinfection with *A. israelii.* Chest wall lesions often are associated with pulmonary or pleural lesions, and lesions of the mandibular area typically are associated with dental caries or periodontal disease. Cases of pneumonia, empyema, osteomyelitis, septic arthritis, brain abscess, cervical lymphadenitis, intra-abdominal abscess, and urinary tract infection have been reported with *A. actinomycetemcomitans* as a sole pathogen or copathogen.

Isolation of the organism is hampered by slow and fastidious growth; a carbon dioxide–enriched environment improves growth. Growth in nutrient broth, such as trypticase soy or Schaedler, can occur without turbidity in blood culture bottles, including radiometric blood culture bottles, or can appear as tiny puffballs growing in the blood cell layer or as granules that adhere to the sides or bottom of the bottle. *A. actinomycetemcomitans* grows on blood or chocolate agar, forming small colonies after up to 7 days of incubation, but grows poorly on MacConkey agar.[4]

Although penicillin or ampicillin has been used commonly to treat infections caused by *A. actinomycetemcomitans*, resistance can occur, and response to ampicillin may be unsatisfactory. Strains are uniformly susceptible to the third-generation cephalosporin antibiotics cefotaxime and ceftriaxone, and either of these agents can be considered the drug of choice. Isolates usually are susceptible to aminoglycosides, rifampin, metronidazole, tetracycline, trimethoprim-sulfamethoxazole, fluoroquinolones, azithromycin, imipenem, and chloramphenicol and generally are resistant to antistaphylococcal penicillins, clindamycin, vancomycin, and erythromycin.[2,3,5,6]

Clinical experience suggests that treatment of endocarditis with penicillin and gentamicin usually is successful. Cefotaxime or ceftriaxone with or without an aminoglycoside or rifampin may be optimal therapy for endocarditis.[3] Oral ciprofloxacin also has been used successfully. Severe periodontal disease usually is treated with mechanical debridement in combination with tetracycline, a fluoroquinolone, or with the combination of metronidazole and amoxicillin.[6]

Bartonella Species

Bartonella bacilliformis is a member of the family Bartonellaceae and the genus *Bartonella*.[7] In addition to *B. bacilliformis*, human pathogens and their main clinical syndromes in this genus include *B. clarridgeiae* (cat-scratch disease), *B. elizabethae* (neurologic, bacteremia, neuroretinitis, endocarditis), *B. henselae* (cat-scratch disease, bacillary angiomatosis, endocarditis), *B. koehlerae* (endocarditis), *B. quintana* (trench fever, bacillary angiomatosis, endocarditis), and *B. vinsonii* subsp. *berkhoffi* and subsp. *arupensis* (endocarditis).[7] *B. bacilliformis* is the etiologic agent of bartonellosis or Carrión disease. *B. bacilliformis* is motile by means of flagella and is transmitted to humans through the bite of the nocturnal sandfly (*Lutzomyia verrucarum*), which is endemic solely in the Andes regions of Peru, Ecuador, and Colombia at elevations between 600 and 2400 meters (2000 and 8000 feet). The incubation period is approximately 2 to 3 weeks (range, 1–12 weeks), and one half of cases occur in children and adolescents.[8–10] A case of possible vertical transmission has been described.[11] The organism adheres to and invades erythrocytes and endothelial cells.

Carrión disease manifests in two distinct stages.[9,12,13] Bacteremic illness (Oroya fever) is the first stage of infection, in which erythrocytes are parasitized, generally resulting in an acute onset of febrile illness associated with severe hemolytic anemia. The most common findings are sustained fever, pallor, malaise, hepatomegaly, and lymphadenopathy.[10] There also is transient immune suppression that can result in disseminated opportunistic infections such as septicemia due to *Salmonella* or other gram-negative bacteria or reactivation and dissemination of latent toxoplasmosis, tuberculosis, or histoplasmosis.[9] Without antibiotic therapy, this stage of infection is fatal in up to 40% of cases, with death due to complications of profound anemia or opportunistic coinfection during the immune deficiency state, or both. Some infected individuals experience fever, headache, and musculoskeletal pain but do not have anemia. Subclinical infection, documented by asymptomatic bacteremia or seroconversion, occurs commonly.[14]

There is a 1- to 2-month or longer interval before the onset of the secondary or eruptive stage of infection.[9] Cutaneous lesions occur after bacterial invasion of capillary endothelial cells with stimulation of cellular proliferation; lesions may contain bacteria.[9] In this stage, one of three types of lesions known as *verruca peruana* are observed: miliary lesions that are the most common and consist of multiple 1- to 4-mm papular, erythematous, round lesions that frequently are on the lower extremities and are pruritic; nodular raised lesions with normal overlying skin; and mular (eruptive-phase) lesions that are >5 mm in diameter, erythematous, and bleed easily.[10] Patients can manifest verruca peruana without a preceding fever.[14]

Diagnosis of Oroya fever can be made through examination of a blood smear, which reveals bacteria adherent to most erythrocytes. The organism can be isolated by inoculation of blood or material from cutaneous lesions onto supplemented brain-heart infusion agar and incubation for 1 to 2 weeks at 25°C to 30°C in 5% carbon dioxide. During an outbreak of acute bartonellosis, detection of the organism on a blood smear had a sensitivity of only 36% compared with bacterial isolation.[15] A serum titer of ≥1 : 256 in an indirect fluorescence antibody assay has been shown to have a sensitivity of 86% for diagnosis of infection in a highly endemic area.[12] Immunoblot and enzyme immunoassay detection of antibodies can be used, although the latter may be most useful for seroprevalence testing.[12] Polymerase chain reaction–based DNA detection in blood is more sensitive than blood culture or examination of a blood smear.[16,17] Diagnosis of verruca peruana is confirmed by biopsy of a lesion that characteristically demonstrates hyperplasia of endothelial cells with swollen nuclei, abundant mitosis, and proliferation of capillaries.

Chloramphenicol, penicillin, tetracycline, or erythromycin is effective treatment for Oroya fever, although spontaneous resolution of erythrocyte parasitism occurs in milder cases after a few days.[8,9] Verruca peruana lesions can be self-limited[11] or may respond to treatment with rifampin or streptomycin or azithromycin[12]; ciprofloxacin can be used, but some isolates exhibit in vitro resistance to fluoroquinolones.[18] Large lesions may require surgical excision.

Cardiobacterium hominis

Cardiobacterium hominis, a microaerophilic, pleomorphic gram-negative bacillus, is one of the HACEK organisms. *C. hominis* is a component of the normal flora colonizing the nose and oral cavity. The principal clinical disease caused by *C. hominis* is endocarditis,[19] but focal soft tissue infection and peritoneal dialysis–related infection have occurred.[20] A case of *C. hominis* bacteremia without endocarditis has been reported in a 28-day-old infant 10 days after a pyloromyotomy with a complicated postoperative course.[21] Endocarditis occurs almost exclusively in adults with preexisting valvular disease. Onset is insidious, often occurring after an oral infection, a dental procedure, or upper gastrointestinal endoscopy. Prosthetic valve endocarditis also occurs.[22] Endocarditis has been reported in a few children, all with underlying congenital heart disease.[23] Common findings of endocarditis are moderate fever, splenomegaly, cutaneous lesions such as petechiae, an elevated erythrocyte sedimentation rate, and mild anemia. Large vegetations and large vessel emboli are characteristic. At least 6 cases of aortic valve endocarditis in adults have been reported due to

Cardiobacterium valvarum, a *Cardiobacterium* species also found in the oral cavity.[24]

Diagnosis is made through recovery of *C. hominis* in blood culture, which takes an average of 5 days of incubation. In broth culture, growth can occur adjacent to the red cell layer in the absence of turbidity and can remain undetected if blind subculture is not performed. The organism grows on sheep blood, chocolate, Mueller-Hinton, and trypticase soy agars, provided that incubation conditions include high humidity and ≥3% CO_2 concentration. In cases of culture-negative endocarditis, the diagnosis has been made using broad-range polymerase chain reaction assay performed on heart valve tissue.[4]

Isolates generally are susceptible to penicillin, ampicillin, cephalosporins, fluoroquinolones (including ciprofloxacin and levofloxacin), chloramphenicol, and tetracycline.[5] However, penicillin-resistant, β-lactamase−producing strains have been described.[25] Susceptibility to vancomycin, aminoglycosides, erythromycin, and clindamycin is variable. Penicillin with or without an aminoglycoside is the therapy of choice for susceptible isolates and achieves a high cure rate; a third-generation cephalosporin with an aminoglycoside is recommended until the results of antibiotic susceptibility testing are available.

Psychrobacter immobilis

Psychrobacter immobilis is a psychrotropic (cold-loving), gram-negative coccobacillus and a member of the family Moraxellaceae that grows best at 20°C. Previously called *Moraxella*-like, *P. immobilis* is related to *Moraxella* and *Acinetobacter. P. immobilis* is associated with fish, processed meat, and poultry and has been isolated from various clinical sites.[26] Clinically significant isolates have been recovered from the blood of a hospitalized adult with AIDS,[27] the blood of a 16-year old boy with chronic granulomatous disease with fatal sepsis,[28] the cerebrospinal fluid of a 2-day-old infant in Micronesia with insidious meningitis, and a conjunctival swab of a 12-day-old infant in Guatemala who developed bilateral purulent conjunctivitis while receiving penicillin.[29,30] The isolate recovered from the 2-day-old infant initially was thought to be *Neisseria gonorrhoeae.* Clinical isolates were recovered on sheep blood agar incubated at 35°C, although growth is best at 20°C. In a recent study of 16 *Psychrobacter* isolates from humans, 10 were identified as *Psychrobacter faecalis,* four were identified as *Psychrobacter pulmonis,* and two could not be identified, findings that led the study authors to question species identification of the reports of clinically significant isolates as *P. immobilis* rather than *P. faecalis* or *P. pulmonis.*[4] Isolates were resistant to penicillin or ampicillin, 2 of 3 were susceptible to gentamicin, and the isolate causing septicemia in the man with AIDS was susceptible to cefotaxime, ceftazidime, piperacillin, amikacin, and ciprofloxacin.

Treponema pallidum (Syphilis)

Sarah A. Rawstron, Sarah J. Hawkes

Four diseases are associated with pathogenic treponemes: (1) venereal syphilis, caused by *Treponema pallidum* subsp. *pallidum;* (2) yaws, caused by *T. pallidum* subsp. *pertenue;* (3) endemic syphilis, or bejel, caused by *T. pallidum* subsp. *endemicum;* and (4) pinta, caused by *T. carateum.* These diseases are thought to have diverged from a single disease 10,000 to 100,000 years ago under the influence of population migration and environmental factors.[1] The pathogenic treponemes cannot be distinguished by serologic tests (nontreponemal and treponemal) or morphologic features,[2] but newer molecular techniques can distinguish *T. pallidum* from the other treponemes.[3] The treponemal diseases evolve over many years in 3 symptomatic stages: a primary stage, marked by a single highly contagious cutaneous or mucous membrane lesion; a secondary stage, the consequence of disseminated organisms, which results in highly infectious cutaneous and mucous membrane lesions, with other organs also affected; an asymptomatic latent stage; and a tertiary symptomatic stage, marked by destructive lesions. These diseases also share an early immune response that modifies the course but does not prevent the disease from progressing. In all cases, a cure is achievable by relatively small doses of penicillin, and humans are the only host.

Treponemal diseases can be differentiated by epidemiology and mode of transmission. Syphilis is caused by *T. pallidum* subsp.

pallidum, occurs globally, and is acquired by sexual contact or congenital infection.

Microbiology and Pathogenesis

Between 1905 and 1910, Schaudinn and Hoffmann identified *T. pallidum* as the cause of syphilis, Wasserman described a diagnostic serologic test, and Ehrlich discovered that salvarsan (an arsenic-based compound) could be used for treatment. *T. pallidum* cultivation in the laboratory still requires propagation in rabbit testes, but application of modern molecular techniques is providing an increased understanding of the interaction between treponemes and the host.[4–7] The *T. pallidum* Nichols strain DNA sequence was published in 1998,[8] and this led to other advances in understanding the structure and function of the organism.[9–11] Molecular techniques led to subtyping of *T. pallidum*,[12] and with increasing discrimination these techniques have improved knowledge of geographic subtype differences and have been used to investigate the epidemiology and spread of syphilis.[13–17] Molecular techniques also have identified significant sequence changes in genes (*tpr*) that cluster in *T. pallidum* subspecies, thus supporting a genetic basis for species classification.[18]

Treponemes are tapered, thin, spiral bacilli (5–15 µm in length, 0.15 µm in width) that exhibit corkscrew locomotion. Infection starts with penetration through minor abrasions in the skin or intact mucous membrane. Only spirochetes that adhere to cells replicate, and cell division occurs every 30 to 33 hours. At least 50 *T. pallidum* organisms are necessary to initiate infection; larger inocula shorten the incubation period. *T. pallidum* structure consists of outer and cytoplasmic membranes, a thin peptidoglycan layer, and 3 endoflagella that lie in the periplasmic space at each end and are responsible for motility.[19] The outer membrane contains a small number of poorly immunogenic transmembrane proteins (*T. pallidum* rare outer membrane proteins, or TROMP), but it does not contain lipopolysaccharide.[20] Highly antigenic lipoproteins (47, 34, 17, and 15 kd) are localized to the subsurface cytoplasmic membrane and are not exposed on the cell surface.[20,21] Host reaction to infection includes cellular and humoral immune responses with more than 60 specific antibodies identified by sodium dodecyl sulfate–polyacrylamide gel electrophoresis. Antibodies directed to the prominent, 47-kd treponemal antigen are the earliest detected by Western blot. Macrophages activated in the presence of specific antibody ingest and destroy large numbers of organisms.[22] However, it is unclear why this process and other immune reactivity hasten healing of the primary lesion but do not halt infection. Various hypotheses suggest that (1) a lack of antigenic reactivity in the outer membrane acts as an immunologic barrier, (2) a change in membrane-bound immunoproteins after dissemination allows organisms to evade antibody-mediated immunity, or (3) treponemes surround themselves with host material and thus delay the host cell response.

Spirochetes preferentially adhere to endothelial cells. Vasculitis with a predominance of mononuclear and plasma cells surrounding the involved vessels is typical of syphilitic lesions. In primary and secondary disease, infectious treponemes are demonstrated easily in lesions. These lesions heal completely, whereas tertiary lesions result in irreversible tissue destruction and fibrosis. Tertiary lesions consist of gummas and cardiovascular and central nervous system (CNS) disease. Gummas are large, granulatomous lesions with a central necrotic mass surrounded by plasma cells, lymphocytes, and monocytes; multinucleated giant cells are not present. Organisms usually are not found in these lesions, which are thought to represent a hypersensitivity phenomenon. Gummas occur in both acquired and congenital disease. Cardiovascular syphilis, another tertiary manifestation, is associated with pathologic changes in the proximal aorta that consist of inflammation-induced obliterative endarteritis of the vasa vasorum leading to medial necrosis. Although inflammatory changes begin in the early stages of infection, clinical manifestations appear 10 to 40 years later. Tertiary neurosyphilis is the result of chronic meningeal inflammation, which affects primarily the meninges but also can involve the brain and spinal cord.[23] Meningeal, meningovascular, parenchymatous, and gummatous neurosyphilis also occurs after untreated congenital infection.

Epidemiology

Syphilis is acquired by sexual contact (including oral sex)[24] and, extremely rarely, by other forms of close contact. Congenital syphilis is a consequence of undiagnosed, untreated, or inadequately treated maternal syphilis. The World Health Organization (WHO) estimates that more than 10 million new syphilis infections occur annually in adults, and more than 1.3 million pregnant women are infected with "active syphilis" each year.[25] Regional rates of seropositivity in pregnant women range from 0.06% in the Middle East to 2.13% in sub-Saharan Africa.

An understanding of transmission, the development of serologic tests to detect asymptomatic infections, and effective penicillin treatment led to a steady decline in the numbers of cases in Western Europe and the United States after a peak during World War II. Reported cases of syphilis in the US remained at low levels until 1986, when the number of cases increased sharply, with the epidemic peaking in 1990.[26] This epidemic was associated mostly with heterosexual transmission, poverty, use of crack cocaine, human immunodeficiency virus (HIV) infection, and minority (predominantly black) ethnic background. Primary and secondary syphilis rates declined from 1990 to 2000, but they have since doubled following the lowest ever rate in 2000.[27] Men accounted for most (91.1%) primary and secondary cases of syphilis in 2013, predominantly men who have sex with men (MSM).[28] However, heterosexual outbreaks continue to occur.[29,30] Geographic variations are seen, with the southern and the western US tending to have higher rates than the rest of the country. Syphilis rates differ among racial and ethnic groups; in 2013, compared with the white population, the rate of primary and secondary syphilis was sixfold higher in the black population and twofold higher in the Hispanic population.[31]

The prevalence of seroreactivity in pregnant women in the US generally is less than 1%. The syphilis epidemic of the early 1990s was associated with an increase in congenital syphilis in the US.[32] In 1988, the US Centers for Disease Control and Prevention (CDC) modified the criteria for case surveillance, which also contributed to increases in reports.[33] The number of cases of congenital syphilis declined after 1991[34]; it increased 23% from 2005 to 2008, primarily in the South,[35] and it fell again from 2009 to 2012. The 2012 nationally reported rate of 7.8 cases of congenital syphilis per 100,000 live births is the lowest recorded rate since 1988. Risk factors for maternal-to-child transmission include lack of prenatal care, first prenatal visit late in pregnancy, and lack of maternal screening and treatment. Because the most important risk is birth to a mother who received no prenatal care, tests for syphilis always should be offered when pregnant women with no record of prenatal screening seek any type of healthcare.[36]

Clinical Manifestations

Acquired Syphilis

Primary Syphilis

Untreated syphilis is a chronic disease evolving in 3 symptomatic stages. Primary syphilis follows approximately 30% of sexual exposures. The incubation period of 1 to 4 weeks is influenced by the number of organisms in the inoculum. The typical primary chancre is a single, painless papule that erodes to form an ulcer with a reddened base and rolled edges. A small inoculum may produce only a papule. Primary lesions can occur in both the genital and oral areas.[24] Women may not notice primary disease because a chancre in the vagina or on the cervix is not visible. Both men and women may ignore a visible lesion because it is painless (unless secondarily infected) and heals completely in 3 to 6 weeks. Painless nonsuppurative enlargement of local lymph nodes accompanies the chancre and can persist for months. Primary lesions contain infectious treponemes, and hematogenous dissemination begins within hours after superficial invasion of organisms and continues throughout primary and secondary disease.

Secondary and Latent Syphilis

Secondary syphilis is a systemic, multiorgan disease that begins 6 to 12 weeks after infection. In 15% of patients, the primary chancre is still present when symptoms of secondary disease begin. Mucocutaneous lesions are common, usually beginning on the trunk and eventually involving most of the body, including palms and soles. Salmon-pink macules, 5 to 10 mm in size, evolve to copper-colored papules that occasionally develop a follicular or pustular appearance. Untreated, skin lesions regress to hypopigmented or hyperpigmented papules that persist for months. Painless generalized lymphadenopathy is found in 85% of patients. In 10% of patients, raised, enlarged, broad, flat papules (condylomata lata) develop in warm, moist areas (vulva, anus, scrotum, and axilla). White-to-grey patches on mucous membranes also are detected in 10% of patients. Fewer than 10% of patients develop transient patchy alopecia and loss of other body hair, including eyebrows and beard, as a result of spirochetal invasion of hair follicles. Arthritis, osteitis, gastritis, hepatitis, splenomegaly, and nephrotic syndrome occur in some patients. CNS involvement is common in secondary syphilis, and, although it is usually asymptomatic, 1% to 2% of patients have acute meningitis. Lukehart and associates,[37] using the rabbit infectivity test (RIT), demonstrated that 40% of patients with early syphilis had either treponemes in the cerebrospinal fluid (CSF) or a reactive CSF Venereal Disease Research Laboratory (VDRL) test result. Common constitutional symptoms of fever, malaise, aches, pains, and sore throat are nonspecific; the diagnosis relies on serologic testing.

Even without treatment, complete resolution of secondary syphilis occurs after 3 to 12 weeks, and disease enters the latent phase. Early latent syphilis is defined as the first year after infection, and late latent syphilis is defined as more than a year after infection. Relapses of secondary syphilis occur in approximately 25% of untreated patients during early latent syphilis, but patients with late latent syphilis are asymptomatic. Although patients are asymptomatic, CSF examination is included in evaluation of latent syphilis because CSF abnormalities correlate with subsequent symptomatic tertiary neurosyphilis.[38] A study evaluating CSF findings in adults with syphilis (most with late latent syphilis and also HIV infection) showed that a serum rapid plasma regain (RPR) titer ≥1 : 32 was predictive of neurosyphilis in all patients, and a $CD4^+$ T-lymphocyte count of ≤350 cells/mm^3 was a second risk factor in adults with HIV infection.[39] Patients' immunity during late latency seems to protect against relapse, but it does not prevent progression of syphilis to the tertiary stage.

Tertiary Syphilis

Tertiary disease occurs in approximately 30% of untreated patients.

Manifestations are divided into 3 main subgroups: neurosyphilis, cardiovascular syphilis, and late benign syphilis (gummas).

Tertiary neurosyphilis includes several clinical syndromes: meningeal, meningovascular, and parenchymatous syphilis (including general paresis and tabes dorsalis). Manifestations appear within a few months of primary infection (meningeal syphilis) or 20 to 30 years later. Meningeal syphilis manifests as cranial nerve palsies, sensorineural deafness, and hydrocephalus. Meningovascular syphilis causes a stroke syndrome resulting from infarction secondary to syphilitic endarteritis, with the middle cerebral artery the most common site. The findings of general paresis can be summarized by the mnemonic PARESIS: personality; affect; reflexes (hyperactive); eye (Argyll Robertson pupils, which react to accommodation but not to light); and abnormalities of sensorium (illusions, delusions, hallucinations), intellect (decreased recent memory, orientation, judgment, insight), and speech.[40] Tabes dorsalis describes the symptoms and signs of demyelination of the posterior column and roots of the spinal cord. Patients can have more than one form of neurologic disease. Treatment can arrest the disease; however, the extent of underlying disease determines whether signs and symptoms resolve.

Cardiovascular syphilis, which occurs from 10 to 40 years after infection, is seen in 10% of patients with tertiary disease. An aneurysm in the ascending portion of the aorta, aortic insufficiency from aortic root dilation, and coronary artery disease are commonly recognized signs.

Benign tertiary syphilis refers to the presence of gummatous lesions in skin, bones, and, rarely, in other organs. Lesions vary in size from microscopic to clearly visible. Gummas are considered benign because they rarely involve vital body structures, but gummas can be destructive. Cutaneous gummas can ulcerate, and bone lesions are painful. Failure to treat or a delay in treatment is associated with disfiguring scars.

Syphilis Associated With Human Immunodeficiency Virus Infection

Syphilis and HIV infection exhibit “epidemiologic synergy,”[41] and coinfection is common.[42–44] The presence of HIV infection is thought to alter the clinical expression of syphilis, response to therapy, and the results of serologic tests.[41] Antibody titers can be higher than expected, but occasionally false-negative results or delayed seroreactivity can occur.[44] In addition, people with HIV infection and early syphilis can be at higher risk for both neurologic complications and treatment failure with currently recommended regimens.[45] Adults with neurosyphilis and HIV infection are less likely to revert from a reactive CSF VDRL test result than are adults without HIV infection.[46] Patients with syphilis should be tested for HIV infection and vice versa. Patients with coinfection require careful and more frequent follow-up.

Mother-to-Child Transmission

Transplacental transmission of syphilis can give rise to a range of adverse outcomes. A meta-analysis of 6 studies found that 52% of pregnancies in women with untreated syphilis led to adverse fetal-neonatal outcomes.[47] This percentage included 21% of pregnancies ending in fetal loss or stillbirth, 9% in neonatal death, and 6% in prematurity or low birth weight. Signs or symptoms of infection (i.e., congenital syphilis) occurred in 15% of maternal infections. These data confirm the findings in historical studies.[48–51] Preventing adverse outcomes of pregnancy (through screening and treatment) is most effective when interventions are delivered in the first 2 trimesters. Women who first attend antenatal care in the third trimester are more than twice as likely to have an adverse outcome compared with women screened and treated in the first 2 trimesters, and in the case of congenital syphilis the risk is almost threefold higher.[52]

Congenital Syphilis

Congenital syphilis is divided into early disease (detected at <2 years of age) and late disease (detected at ≥2 years of age). Most children with early disease are <3 months of age.

Transmission rates are higher (60%–90%) in untreated maternal primary or secondary syphilis, decreasing to 40% in early latent syphilis and to <10% in late latent syphilis. Placental and umbilical cord abnormalities are common; the placenta can appear pale and large, and immature villi and focal villitis with endovascular and perivascular proliferation are seen microscopically. Changes are not pathognomonic, although necrotizing funisitis within the matrix of the umbilical cord is considered highly indicative of syphilis. *T. pallidum* usually can be identified in tissue specimens by silver or immunofluorescent stains.

Early Disease

Congenital syphilis lacks a primary stage because it is a consequence of hematogenously disseminated *T. pallidum* and is similar to secondary syphilis. The typical stillborn or highly symptomatic newborn is born prematurely, has an enlarged liver and spleen, has skeletal involvement, and often has pneumonia (pneumonia alba) and skin lesions. Less severely affected infants have a variety of signs. Hepatomegaly is reported in almost 100%, and biochemical evidence of liver dysfunction usually is observed; serum alkaline phosphatase levels are elevated, but elevation of hepatic transaminase levels may occur only after treatment is initiated and an immune response occurs.[53] Approximately 40% to 60% of infected infants have 1 or more of the following: hepatosplenomegaly, rash, generalized lymphadenopathy, skeletal abnormality, or nasal discharge. The rash usually is maculopapular and initially erythematous, changing to a papular desquamating rash of coppery color and often involving the palms and soles. Petechial lesions, secondary to thrombocytopenia, also can be seen. Pemphigus syphiliticus is a rash unique to infected newborns and consists of vesiculobullous lesions, containing many organisms, that rupture easily and leave a macerated appearance.

Radiographic abnormalities are common in early syphilis; 95% of symptomatic infants and up to 20% with asymptomatic disease have bony abnormalities.[54] Lesions include metaphysitis, periostitis, and osteitis. Findings are symmetric and involve multiple long bones; the lower extremities are almost always affected. Metaphyseal lesions (osteochondritis) (Fig. 182.1A), which vary from punctate lucencies to more destructive changes, are seen earlier than periostitis. Wimberger sign ("cat bite") describes osteitis and destruction of the proximal medial tibial metaphysis (see Fig. 182.1B), and although it is occasionally seen in other conditions, this sign is highly suggestive of congenital syphilis. Occasionally, the lesions are painful, resulting in pseudoparalysis of the affected limb (pseudoparalysis of Parrot). Periostitis appears radiographically as multiple layers of periosteal new bone formation.

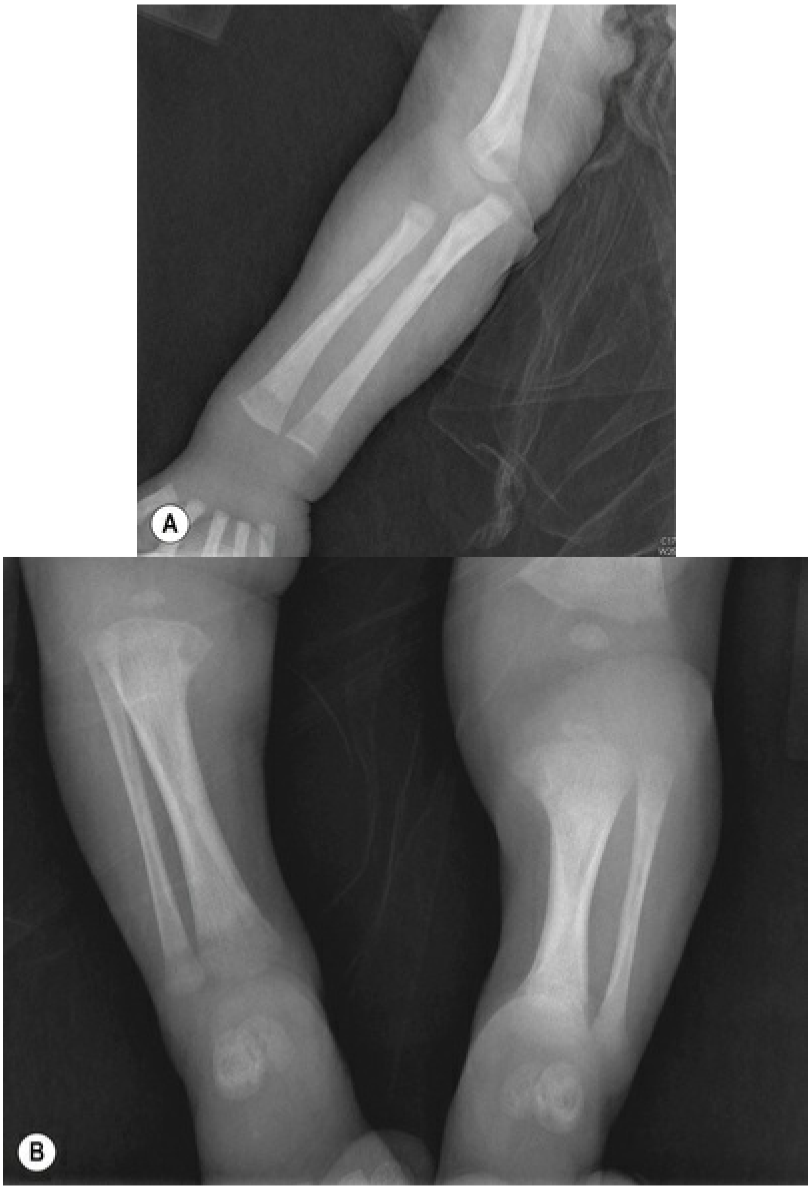

FIGURE 182.1 **Plain radiographs of an infant with congenital syphilis. Note decreased mineralization of the metaphyses of long bones of the (A) upper and (B) lower extremities, as well as bilateral lytic lesions of the talus, calcaneus, and (B) proximal tibia (Wimberger sign) medially.** **(Copyright by J. H. Brien ©.)**

The CSF is abnormal in 50% of symptomatically infected infants and in up to 10% of asymptomatic infants. The diagnosis of neurosyphilis is made with a reactive CSF VDRL test result or with abnormal elevation of CSF white blood cell (WBC) count or protein levels (although the definition of “abnormal” varies).[41] However, this standard for diagnosing congenital neurosyphilis is insensitive in comparison with RIT.[55] Although no single laboratory test identifies all patients with neurosyphilis as confirmed by RIT, most infants with neurosyphilis are identified by conventional testing (physical examination, complete blood count, bone radiography, and lumbar puncture); the addition of immunoglobulin M (IgM) immunoblotting and polymerase chain reaction (PCR) tests identifies almost all others. Even when CSF is abnormal, neurologic symptoms or signs usually are absent. Rhinitis, or “snuffles,” occurs rarely now and consists of a clear nasal discharge (containing many spirochetes) that becomes chronic and turns bloody as a result of mucosal erosion. Nephrotic syndrome, which occurs less commonly than other manifestations, is caused by immune complex disease rather than by direct invasion by treponemes.[56] Hematologic disturbances are seen in symptomatic infection; more than 75% of infants have anemia, and 50% have an elevated WBC count with significant monocytosis.

The appearance of symptomatic congenital syphilis after discharge from the nursery most often is caused by a failure to perform maternal serologic testing at delivery or to obtain results of serologic tests before discharge. Infants born to recently infected mothers whose serologic test results are negative at delivery escape detection until these children become symptomatic. In such cases, onset of symptoms before 3 months of age is expected, with a spectrum of disease similar to that seen in symptomatic newborn infants, except that fever can be a prominent initial complaint.[57]

Late Disease

Late congenital disease is seen in patients ≥2 years of age and is not considered contagious. Malformations in bones (frontal bossing, saddle nose [a result of osteochondritis], and saber shins), teeth (Hutchinson peg-shaped, notched central incisors, mulberry multicusped first molars), and skin (rhagades, or linear scars, fanning out from the corner of the mouth) result from growth disturbances in these organs. Other manifestations (e.g., interstitial keratitis and eighth nerve deafness) result from longstanding chronic inflammation. Symmetric, chronic painless swelling of the knees (Clutton joints) has been described in a few affected patients. Asymptomatic neurosyphilis is more common in these children than is symptomatic disease. Pathologic changes in the nervous system and mental, motor, and sensory deficits are similar to those seen in acquired tertiary disease. During the 19th century, Hutchinson noted that the triad of defects in the incisors, interstitial keratitis, and eighth nerve deafness was unique to congenital syphilis. A more recent review, encompassing 271 cases of congenital syphilis, reconfirmed the pathognomonic constellation.[58]

Diagnosis

Antibody Tests

Serologic testing is the standard method to identify asymptomatic infection and confirm clinical diagnosis. Seroreactivity is present in all stages of disease but cannot be used to distinguish among stages. Serologic tests include nontreponemal and treponemal tests. The traditional algorithm for testing is a nontreponemal test followed by treponemal test.

Nontreponemal Tests

Nontreponemal tests are performed easily and detect IgM and IgG antibodies to cellular lipids and lecithin. The 2 commonly used nontreponemal tests are the RPR test and the VDRL test. Reactive sera produce flocculation of the antigenic material. Nontreponemal antibodies appear from 4 to 8 weeks after infection; seroreactivity is present in 70% of patients within 2 weeks of the eruption of a chancre and in 100% of patients who have secondary and latent disease. No nontreponemal serologic test is reactive in the first weeks of infection. Nontreponemal tests can be quantified by serial serum dilution; a 2-tube (fourfold) change or more in reactivity is significant. A fourfold to eightfold decrease in titer 6 to 12 months after successful treatment is expected for all patients with early disease (primary and secondary), with a slower decline in treated patients with later stages of disease.[59] A titer that does not fall or that rises after an initial significant decline indicates inadequate therapy or new infection. Seroreversion to negative occurs after treatment in some patients and depends on the original titer and the stage of disease during therapy.[59] For other patients, titers fall significantly but persist at low levels; such patients are considered to be serofast. Untreated people remain seroreactive for life, although titers fall with time even without treatment. The VDRL test is primarily used for testing CSF (and is the only test approved for testing CSF). A false-positive nontreponemal serum test result usually has a titer ≤1 : 4 and can occur in patients with connective tissue disorders, in patients with viral diseases (e.g., hepatitis, chickenpox, and infectious mononucleosis), in approximately 10% of injecting drug users, and, occasionally, in pregnancy. The prozone effect describes a false-negative reaction that results from excess antibody concentration that inhibits formation of the antigen-antibody lattice needed for flocculation. This effect is overcome by serial serum dilutions. The prozone effect must be considered when a neonate shows signs of congenital syphilis and the mother is seronegative. Nontreponemal tests are useful for screening and monitoring therapy. Treponemal tests are required for confirmation that the nontreponemal reactivity is caused by syphilis or another treponemal infection.

Treponemal Tests

Older treponemal tests include the fluorescent treponemal antibody-absorbed test (FTA-ABS), the microhemagglutination test for *T. pallidum* (MHA-TP), and the *T. pallidum* particle agglutination test (TP-PA). Characteristics of treponemal tests are positivity slightly earlier than nontreponemal tests, positivity for life, and an inability to reflect activity of infection. False-positive treponemal test results can occur in various conditions, especially spirochetal infections, including Lyme disease (in which the nontreponemal test shows negative results).[60] Newer treponemal assays, including enzyme immunoassays (EIAs),[61,62] chemiluminescence immunoassays (CIAs), and recombinant *T. pallidum* antigen tests[63] are automated and easily adapted for population-level screening. In so-called reverse sequence testing, an automated treponemal test is used for screening (EIA/CIA), followed by confirmation testing in reactive specimens by using a second different treponemal test and a quantitative RPR or VDRL test.[64,65] The details of reverse sequence testing vary between Europe and North America.[65–67] Reverse sequence testing is not recommended by the CDC.[41,67] An analysis by the CDC of data from 5 laboratories from 2006 to 2010 showed significant discordant results, with 57% of patients with positive treponemal EIA/CIA results having a nonreactive RPR test; among these patients, 32% did not have a confirmatory TP-PA test result.[67] Reverse sequence testing increases false-positive results (particularly in low-prevalence populations), and it can be more expensive because of the increased number of confirmatory tests, follow-up, and overtreatment.[67–71] In many resource-poor settings a new generation of point-of-care treponemal tests, which use whole blood, have been evaluated and are being promoted as a component of syphilis control programs among higher-risk populations, as well as in prenatal care services (e.g., as initial screening tests with a nontreponemal test as confirmatory).[72–74]

Tests for Organisms

The most sensitive diagnostic method for identifying viable treponemes in CSF and exudate is the RIT,[75] which involves serial passage of infected material in the testes of rabbits. Although not clinically useful, this test is the gold standard for measuring infectivity and for determining the sensitivity of other *T. pallidum* detection methods, including newer tests such as PCR.[55] Darkfield microscopy can be used to examine exudates; motile organisms too thin to be seen by light microscopy can be visible. Drawbacks include the need for specialized equipment, personnel skilled in its use, and urgency of examination before drying immobilizes treponemes.

Treponemes in tissue specimens can be visualized with silver stain, but fluorescent antibody or immunohistochemistry tests are more specific. The direct fluorescent antibody *T. pallidum* (DFA-TP) test uses a fluorescein-labeled rabbit or monoclonal *T. pallidum* antibody for identifying organisms in body fluids and exudate, and it has been modified for use on biopsy and autopsy material.[76] Newer PCR tests have high sensitivity and specificity but may not be readily available commercially.[77–79]

Diagnosis of Congenital Syphilis

Definition

To optimize testing and to maximize treatment of potentially infected infants, the CDC developed a broad definition of congenital syphilis. A *confirmed* case is one with laboratory confirmation.[80] A *presumed* case (symptomatic or asymptomatic) is as follows: (1) an infant born to a mother with reactive serologic test results whose mother was not treated, was inadequately treated, or was treated <1 month before delivery; or (2) an infant who has physical signs, CSF abnormalities, or evidence of congenital disease on skeletal radiographs.[33,80] The definition of a presumed case of congenital syphilis ensures that all patients with possible cases are treated, although all may not be infected.

The WHO defines congenital syphilis as follows: (1) a stillbirth, live birth, or fetal loss at >20 weeks of gestation or >500 g to a syphilis-seropositive mother without adequate syphilis treatment; or (2) a stillbirth, live birth, or child <2 years of age with microbiologic evidence of syphilis infection, which includes any 1 of the following: demonstration by darkfield microscopy or fluorescent antibody detection of *T. pallidum* in the umbilical cord, the placenta, nasal discharge, or skin lesion material; detection of *T. pallidum*–specific IgM in serum; or a positive serologic nontreponemal titer at least fourfold that of the mother.[81]

Both the CDC and WHO definitions include a range of outcomes of pregnancy in women with positive syphilis serologic results; in other words, syphilis should be considered not only in live-born infants, but also in stillbirths and any fetal loss after 20 weeks of gestation (with a fetal weight >500 g). Treatment should include the mother, her sexual partner or partners, and infants as appropriate.[82]

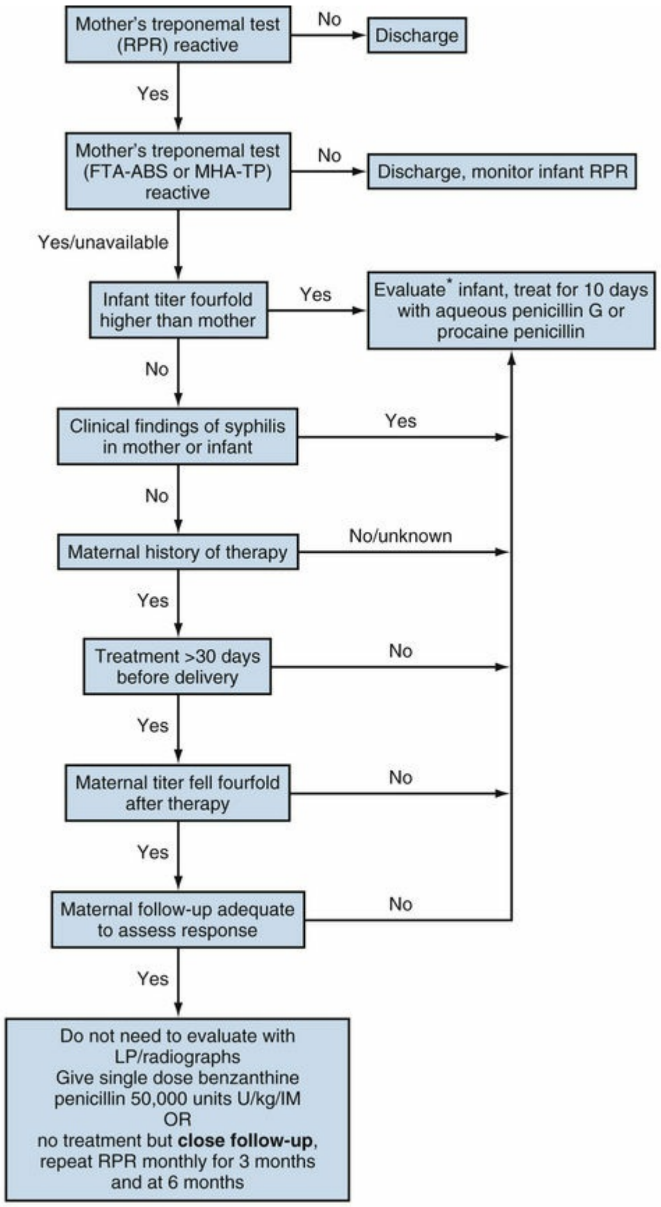
Testing Considerations

A screening test for syphilis should be performed at the first antenatal visit and repeated at delivery. In high-risk patients, an additional serologic test at the beginning of the third trimester also is suggested.[83] In 1 report, 13% of women found to be seroreactive at delivery were seronegative earlier in the pregnancy.[57] Sexual partners of syphilis-seropositive women also should be offered treatment.

Several problems confound the diagnosis of congenital syphilis, particularly in an asymptomatic infant. Results of any nontreponemal or treponemal test performed on the infant may reflect maternal antibody titers and do not prove congenital infection.[84,85] Passively acquired nontreponemal antibody usually reverts to negative by 6 months, whereas treponemal antibody can persist for 1 year or longer. An infant treated for congenital syphilis could have similar test results. Children who retain reactive nontreponemal and treponemal antibody at 18 months of age or older should be re-evaluated (see the later section on acquired syphilis).[86] Treponemal IgM tests can identify the infant's production of antibodies (i.e., congenital infection), but not every infant with congenital syphilis produces IgM antibodies.[87] Identification of treponemes in lesions, or in the placenta or umbilical cord, can identify infected infants, but these findings are not seen in every infected infant, and the tests are not available readily. Additional tests, such as CSF VDRL and skeletal radiographs, can identify infected asymptomatic babies, but the sensitivity of these tests is not known.

Evaluation

The evaluation of each newborn infant whose mother has a positive serologic test result for syphilis requires careful and individualized attention (Fig. 182.2). The CDC recommends that all infants born to seroreactive mothers should have a quantitative nontreponemal serum test performed (because umbilical cord blood can be falsely positive or negative).[41,85] In addition to obtaining the maternal history, all infants born to seroreactive mothers should be examined for physical evidence of congenital syphilis (e.g., hepatosplenomegaly, rash). Examination of the placenta and umbilical cord by a pathologist using direct fluorescent antibody is suggested. Additional tests to evaluate congenital syphilis (CSF analysis by VDRL, WBC count, protein level, long bone radiographs, complete blood cell count, and serum hepatic enzyme levels) should be performed if the infant is suspected of having congenital syphilis or has any abnormal physical findings.



Mother's treponemal test (RPR) reactive
No
Discharge
Yes
Mother's treponemal test (FTA-ABS or MHA-TP) reactive
No
Discharge, monitor infant RPR
Yes/unavailable
Infant titer fourfold higher than mother
Yes
Evaluate* infant, treat for 10 days with aqueous penicillin G or procaine penicillin
No
Clinical findings of syphilis in mother or infant
Yes
No
Maternal history of therapy
No/unknown
Yes
Treatment >30 days before delivery
No
Yes
Maternal titer fell fourfold after therapy
No
Yes
Maternal follow-up adequate to assess response
No
Yes
Do not need to evaluate with LP/radiographs
Give single dose benzanthine penicillin 50,000 units U/kg/IM
OR
no treatment but **close follow-up**, repeat RPR monthly for 3 months and at 6 months

*Evaluation includes physical examination, pathologic study of placenta (with direct fluorescent antibody [DFA] test, if possible) and cerebrospinal fluid (including Venereal Disease Research Laboratory [VDRL] test, white blood cell count, protein levels), complete blood cell count, and other tests as clinically indicated (e.g., long bone and chest radiographs, liver function tests, cranial ultrasonography, ophthalmologic examination, and auditory brainstem response).

FIGURE 182.2 Assessment and management of congenital syphilis. FTA-ABS, fluorescent treponemal antibody-absorbed test; IM, intramuscularly; LP, lumbar puncture; MHA-TP, microhemagglutination test for *Treponema pallidum*; RPR, rapid plasma reagin. (Data from Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2010. MMWR Recomm Rep 2010;59[RR-12]:26–39; and American Academy of Pediatrics. Syphilis. In: Pickering LK, Baker CJ, Kimberlin DW, Long SS [eds]. Red Book: 2009 Report of the Committee on Infectious Diseases, 28th ed. Elk Grove Village, IL, American Academy of Pediatrics, 2009, pp. 638–651.)

Unfortunately, confirming a diagnosis of congenital syphilis has not improved in the US because validated serologic tests for *T. pallidum* IgM antibodies, and tests for treponemal antigens or DNA, have not become available widely. Despite carefully designed screening programs, some neonatal infections are missed because recently acquired maternal infection can be associated with seronegativity at birth in both mother and neonate.[57]

Diagnosis of Acquired Syphilis in Children

Children can acquire syphilis after the neonatal period, predominantly from sexual abuse, but this is rare.[88] Adolescents can acquire syphilis through sexual activity, and they should be evaluated and managed as appropriate for the stage of syphilis. In younger children, determining whether syphilis is congenital or acquired can be difficult in the absence of physical findings or a clear history.[89,90] Similarly, children immigrating from areas of the world endemic for other treponematoses who have reactive serologic tests pose a diagnostic problem.[91] Differentiating yaws from syphilis (both congenital and acquired) may not be possible, even if additional information is available. Important information that can help in decision making include the maternal history of syphilis, titer results and treatment during pregnancy, maternal and infant titers, and evaluation and treatment for congenital syphilis at birth. If the child has no physical findings, a reactive nontreponemal test result (confirmed by treponemal test) can indicate either congenital or acquired disease. In such a case, the child should be evaluated fully for congenital syphilis, including lumbar puncture to evaluate for possible neurosyphilis, skeletal radiographs, an eye examination, and complete blood cell count. Positive results on an FTA-ABS test can persist in infants appropriately treated for congenital syphilis at birth.[86] If the nontreponemal test result is negative, further workup is not recommended; however, if the nontreponemal test result is positive at ≥18 months, the infant should be re-evaluated fully and treated for congenital syphilis.

Treatment and Follow-Up

Syphilis has been treated successfully since the late 1940s using penicillin. Treatment regimens are updated regularly by the CDC (http://www.cdc.gov/std/treatment), and the American Academy of

Pediatrics[83] (Table 182.1).[41,92] Treatment failures are uncommon; more than 95% of otherwise healthy patients with primary disease and approximately 90% of patients with secondary and early latent disease are cured with a single injection of benzathine penicillin G. Failure to cure acquired disease may be more common in patients with symptomatic secondary disease and in patients infected with HIV infection. However, the data suggesting a different response to syphilis treatment in HIV-infected patients is largely from the pre-antiretroviral treatment era.[37,45,93] Data that include HIV-infected patients receiving antiretroviral treatment show a good response and reduced failure of recommended therapy,[94,95] although patients with syphilis and HIV infection should still be closely monitored for appropriate treatment response.[96,97]

TABLE 182.1
Syphilis Therapy

Condition	Treatment[a]	Comments
ACQUIRED DISEASE		
Primary, secondary, early latent disease (normal host)	Adults: 2.4 million U BPG × 1 Children: 50,000 U/kg BPG × 1	Penicillin-allergic adult can be treated with doxycycline 100 mg bid for 2 wk or tetracycline 500 mg orally q6h; penicillin-allergic child (<age 8 yr) should be desensitized and treated with penicillin
Late latent disease, disease of unknown duration, gumma, aortitis	Adults: 2.4 million U BPG weekly × 3 Children: 50,000 U/kg BPG weekly × 3	Penicillin-allergic adult can be treated with doxycycline 100 mg bid or tetracycline 500 mg q6h orally for 28 days Perform lumbar puncture if neurologic or ophthalmologic signs or symptoms, active tertiary syphilis or treatment failure; if CSF is abnormal, treat for neurosyphilis
Neurosyphilis	Adults: 18–24 million U/day APG, divided into q4h doses (3–4 million U/dose) or continuous IV infusion for 10–14 days; or APPG 2.4 million U once daily IM and probenecid 500 mg 4 times daily for 10–14 days	Penicillin-allergic patients should be desensitized and treated with penicillin
	Children: 200,000–300,000 U/kg/day APG divided into q4–6h doses for 10 days	
Pregnancy	Treat as for acquired disease; see text	Penicillin is the only drug used in pregnancy; penicillin-allergic patients should be desensitized and treated with a 10-day course of APG
HIV infection	Treat as for acquired disease; see text	Perform lumbar puncture for same indications as for late latent disease; strongly consider lumbar puncture if serum

		nontreponemal antibody titer does not fall fourfold 6–12 months after therapy; if CSF is abnormal, treat for neurosyphilis; if penicillin-allergic, desensitize and treat with APG penicillin
CONGENITAL DISEASE	≤4 wk of age: 100,000 U/kg/day APG IV divided into q12h doses during first 7 days of life and 150,000 U/kg/day APG divided into q8h doses thereafter for total of 10 days *or* 50,000 U/kg once/day APPG IM × 10 days >4 wk of age: 200,000–300,000 U/kg/day APG divided into q4–6h doses × 10 days	See text

[a] Children who weigh >50 kg are treated with adult dosing schedule.

APG, aqueous penicillin G; APPG, aqueous procaine penicillin G; BPG, benzathine penicillin G; CSF, cerebrospinal fluid; HIV, human immunodeficiency virus; IV, intravenous(ly); IM, intramuscularly.

From Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2010. MMWR Recomm Rep 2010;59(RR-12):26–39.

Prenatal treatment that has effectively cured maternal disease sometimes fails to prevent adverse pregnancy outcomes.[98,99] In 1 report, 60 (14%) of 437 infants with congenital disease were born to mothers who were treated during pregnancy.[99] Failures were highest with treatment in the third trimester, especially in the month before delivery. Failure of maternal treatment also is associated with preterm delivery.[100] Pregnant patients should be treated only with penicillin regimens, appropriate for the stage of syphilis.

Patients with congenital infection, either proved or presumed, are treated with a 10-day course of aqueous penicillin G or procaine penicillin G. Azimi and colleagues[101] noted that, in some neonates, the level of penicillin in CSF 18 to 24 hours after a dose of procaine penicillin G was lower than that considered to be treponemicidal; these investigators suggested that, for infants with severe or proven CNS disease, aqueous penicillin G could be superior therapy. CDC guidelines suggest that benzathine penicillin G could be used when the risk of congenital syphilis is low (i.e., a well infant with a normal examination born to a mother treated in the month before delivery). However, the development of congenital syphilis in some infants whose mothers were treated toward the end of pregnancy and the failure of benzathine penicillin G to cure early congenital syphilis suggest that such infants could optimally be treated with a 10-day regimen of aqueous or procaine penicillin G.[98,99,102] In the future, tests currently under investigation to detect the presence of spirochetes or spirochetal DNA in CSF should better determine CNS infection and provide a more precise basis for therapy.[103]

Patients who are allergic to penicillin but not pregnant can be given tetracycline or doxycycline for early, latent, and tertiary disease that has not affected the CNS. Because oral tetracycline or doxycycline must be given daily for 2 weeks, it should be used only when adherence and follow-up are ensured. Children with acquired syphilis who are <8 years of age, pregnant women, HIV-infected patients, and adults with later stages of syphilis or tertiary disease who are allergic to penicillin should be desensitized and treated with penicillin.[41] Although single-dose azithromycin in the treatment of early syphilis showed equivalent treatment efficacy compared with the recommended penicillin regimen,[104] macrolide resistance has been identified in *T. pallidum* in several geographic areas (associated with mutations in the 23S rDNA [A2058G and A2059G]).[105–108] In addition, treatment failures resulting in congenital syphilis have been reported with the use of azithromycin in pregnant women.[109] Macrolides are not an acceptable alternative therapy for penicillin-allergic pregnant women.

The Jarisch-Herxheimer reaction, the major complication of therapy, occurs most commonly among patients with early syphilis, both children and adults. Fever is the major symptom and can be accompanied by headache and myalgia. Hypotension, tachycardia, and an increase in respiratory rate occur in some patients. During pregnancy, the Jarisch-Herxheimer reaction can cause uterine contractions and decreased fetal activity, and occasionally it can result in premature delivery or fetal death.[110]

Patients with primary, secondary, or early latent syphilis should be re-examined clinically and serologically at 6 and 12 months after therapy. Late latent syphilis requires a further re-examination at 24 months after therapy. Patients with HIV infection and syphilis require careful clinical and serologic follow-up at 3, 6, 9, 12, and 24 months after therapy for early syphilis and at 6, 12, 18, and 24 months for patients with latent syphilis. Infants with congenital syphilis and all seroreactive infants, regardless of infection status, should be examined and have repeated quantitative nontreponemal tests every 2 to 3 months until nonreactivity is documented.

Prevention

Prevention of congenital syphilis requires a multifaceted approach,[111,112] including the following: (1) information, education, and counseling regarding syphilis transmission and prevention (including promotion of safer sexual activity); (2) adequate and equitable health systems, including access to comprehensive reproductive and sexual healthcare for those at highest risk of infection; (3) partner management (notification and treatment) for all sexual partners of primary patients; (4) early access to prenatal care for all pregnant women, including syphilis testing at the first visit and at the time of delivery, and adequate treatment; (5) detection and treatment of congenital infection before appearance of symptoms; and (6) recognition and treatment of symptomatic infection when it occurs after the neonatal period. A systematic review and meta-analysis of implementing these types of interventions showed that the syphilis-attributable incidence of stillbirth and perinatal death could be reduced by 50%.[74]

Key Points

Epidemiology, Clinical Features, Diagnosis, and Treatment of Syphilis

Epidemiology

- Worldwide
- Epidemiology variable by geographic region, by sexuality (more common in US in men who have sex with men), and among some minority populations
- Acquired transplacentally (mother to child transmission) or by sexual contact

Clinical Features

- Primary stage: painless genital chancre with regional lymphadenopathy

- Secondary stage: disseminated disease with rash (especially palms and soles), constitutional symptoms, condylomatous lesions

- Tertiary stage: cardiovascular, neurologic, gummas

- Mother-to-child transmission results in stillbirth, late fetal loss, low birth weight baby, neonatal death, and infant with congenital syphilis.

- Early congenital syphilis (<2 years): symptomatic (hepatosplenomegaly, small for gestational age, rash, bone, cerebrospinal fluid findings), or asymptomatic

- Late congenital syphilis (≥2 years): bone or dental findings, hearing loss

Diagnosis

- Serology: nontreponemal test (RPR, VDRL) for screening and to follow adequacy of treatment; treponemal test (FTA-ABS, TP-PA) for confirmation of positive nontreponemal test result as caused by syphilis

Treatment

- Penicillin

- Alternative: doxycycline (≥8 years old and not pregnant)

- Follow nontreponemal titers to monitor for success (i.e., fourfold decrease in titer)

Prevention

- Promote comprehensive sexuality education and safer sexual practice (e.g., use of barrier methods)

- Treat infected people and sexual partners

- Screen all pregnant women at first antenatal visit; treat and follow infected women

FTA-ABS, fluorescent treponemal antibody-absorbed test; RPR, rapid plasma reagin; TP-PA, *Treponema pallidum* particle agglutination; VDRL, Venereal Disease Research Laboratory.

Other *Treponema* Species

Sarah A. Rawstron

Yaws

Yaws (*Treponema pallidum* subsp. *Pertenue* infection) is an infectious disease of childhood. It is seen in warm, humid tropical regions in rural, often inaccessible areas, associated with poverty, overcrowding, poor hygiene, and lack of access to health services. "Yaws begins where the road ends."[1] Endemic areas include Africa, Southeast Asia, the Western Pacific, and South and Central America.[2] Yaws is also known as framboesia, pian, parangi, paru, bouba, and buba.

Mass treatment campaigns of approximately 50 million people in the 1950s and 1960s eradicated yaws from many areas. However, a resurgence of the disease occurred in the 1980s, particularly in parts of West and Central Africa and Southeast Asia.[3,4] The successful yaws eradication campaign in India[5] renewed energy and efforts to eliminate yaws worldwide. In 2012 the World Health Organization (WHO) devised the Morges Strategy to eradicate yaws by 2020.[6] This plan includes treating entire communities with 1 dose of azithromycin with close follow-up for 3 years with serosurveys and retreatment if necessary. A successful mass treatment campaign in Papua New Guinea using this strategy strongly supports this approach.[7]

Clinical Manifestations

Yaws is passed from child to child through nonsexual contact with primary or secondary skin lesions. The primary lesion, the mother yaw, generally occurs on the lower half of the body at sites of minor trauma. The lesion begins as a painless, erythematous papule that enlarges, ulcerates, and becomes covered by a honey-colored crust 9 to 90 days after inoculation. Painless, regional lymphadenopathy occurs. The primary lesion heals after several weeks to months.

Organisms disseminated during the primary stage form the basis of secondary disease. This stage manifests as multiple cutaneous lesions (daughter yaws), which resemble the mother yaw both clinically and histologically but are smaller, as well as painful periostitis involving bones of the extremities, especially the hands and feet. Secondary lesions heal spontaneously and without scarring.

The pathologic features of primary and secondary lesions resemble those seen in sexually acquired syphilis. Latent yaws is characterized by intermittent relapses of skin lesions at intervals for up to 5 years, but congenital infection is not seen. Experimental infections of guinea pigs have confirmed the lack of congenital infection in yaws.[8]

Tertiary yaws, which develops in approximately 10% of untreated patients after several years, consists of destructive lesions of bone, cartilage, soft tissue, and skin. Characteristic findings are as follows: palmar-plantar hyperkeratosis; goundou, a rare lesion in which symmetric involvement of the nasal processes of the maxilla leads to excessive bone formation and obstruction of the airway; gangosa (destructive ulcerative rhinopharyngitis); and chronic osteitis leading to saber tibia.

Diagnosis

In endemic areas, the diagnosis is made clinically. In addition, treponemes are identified easily with darkfield microscopy of exudate from primary and secondary lesions, and serologic tests for syphilis are reactive. Point-of-care tests that detect both treponemal and nontreponemal antibodies appear promising.[9] Polymerase chain reaction testing also can be used to identify *T. pallidum pertenue,* as well as macrolide resistance,[10] but this test is not readily available clinically. The Centers for Disease Control and Prevention has recommended screening children who come from areas of the world with endemic treponematoses by using nontreponemal serologic tests.[11]

Endemic Syphilis (Bejel)

Endemic syphilis (bejel), caused by *Treponema pallidum* subsp. *endemicum,* is found in areas with a hot, dry climate in North Africa, Southwest Asia, and the eastern Mediterranean. Until 1960, this disease also was present in Bulgaria and the former country of Yugoslavia; a treatment and prevention program eliminated these foci.

Infection occurs in childhood and is acquired from contaminated fomites (e.g., communal drinking vessels) or through oral-oral contact. The primary lesion, a small, painless papule or ulcer in the mouth, usually is not detected. The secondary stage, resulting from treponemal dissemination, is characterized by numerous, highly infectious mucous membrane patches, often accompanied by hoarseness from syphilitic laryngitis, and regional lymphadenopathy. Axillary and anogenital condylomata can be seen, and osteoperiostitis of the long bones can cause nocturnal leg pain.

After a latent period, untreated bejel progresses to tertiary symptoms in most patients; sometimes it is characterized by destructive lesions (gummas) involving the nasopharynx, skin, and bones, but involvement of other organs, including the eye, can occur. As living conditions improve in endemic areas, a form of the disease has been observed in which the number of lesions and the signs and symptoms are less severe.

The disease has some similarities to sexually acquired syphilis. However, the method of acquisition, the site of the primary lesion, the lack of congenital disease, and the absence of cardiovascular and neurologic symptoms in endemic syphilis differentiate the 2 diseases. When symptoms consistent with either endemic syphilis or venereal syphilis occur in an area where both diseases exist, epidemiologic features of an outbreak can be useful for differentiation.

Pinta

Pinta (*Treponema carateum* infection), which occurs only in the Western Hemisphere, has been described in Central and South America, Cuba, and the Caribbean islands. Control with penicillin has made pinta a rare disease. Pinta begins during childhood and adolescence, and the clinical stages are confined to the skin, with lymphadenopathy the only systemic manifestation. The word *pinta* is taken from the Spanish verb to paint and is indicative of the various colors seen as the skin lesions mature: red, white, violet, blue, brown, or black.

Pinta is transmitted through contact with broken skin, and the primary lesion occurs mainly on the lower leg, dorsum of the foot, forearm, or back of the hands. One to 8 weeks after inoculation, a tiny erythematous papule or cluster of papules appears and then enlarges and coalesces. An irregular and heaped border surrounds the erythematous, scaly central lesion. Dissemination from the primary site results in secondary skin lesions known as *pintids,* which develop 3 to 9 months after the initial inoculation and before the primary lesion has healed completely. Secondary lesions are indistinguishable clinically and histologically from the primary lesion.

Primary and secondary lesions are highly contagious and heal slowly. Three months to many years later, tertiary disease manifests as achromic, atrophic lesions. These lesions are not considered infectious.

Treatment

Treatment of all nonvenereal treponematoses once was the same, namely a single dose of benzathine penicillin (1.2 million units for adults and 0.6 million units for children younger than 10 years of age). Family members, contacts, and patients with latent infection also receive the same dose as those with active disease. Later treatment results in slower healing, and serologic reactivity can persist.

Newer, alternative therapies for yaws have been studied. In Guyana, oral penicillin V therapy for 7 to 10 days appeared promising.[12] The most promising newer oral therapy is a single dose of azithromycin (30 mg/kg; maximum dose 2 g), which was shown to be noninferior to benzathine penicillin.[13] A mass treatment campaign using this regimen has been successful,[7] and it demonstrated that the Morges Strategy[6] (which includes azithromycin therapy) is an effective approach to reach the WHO yaws eradication goal by 2020.[14] Because of the concern that macrolide resistance may develop (as has occurred in *T. pallidum* subsp. *pallidum* infection in some areas), surveillance for macrolide resistance during mass treatment campaigns will be needed as part of the eradication plan.[15]

Leptospira Species (Leptospirosis)

Eugene D. Shapiro

Pathogenesis

The *Leptospira* genus consists of a group of motile, finely coiled, catalase-producing spirochetal bacteria that are obligate aerobes. The *Leptospira* genus is classified into at least 20 species and genomospecies. *L. biflexa* is a free-living saprophytic organism that is found in water and soil and does not cause human disease. At least 8 other species, *including L. interrogans,* are highly pathogenic for humans, and several others are intermediately pathogenic. Serologic classification is important because specific serogroups (>25) and serovars (>250) are associated with specific animal species and vary in their pathogenicity and virulence for humans. The application of molecular genetic techniques to understanding the biology of the organism and the mechanisms by which *Leptospira* organisms are pathogenic for humans is beginning to provide new insights into this ancient disease.[1] Stimson, who first saw the organism under the microscope in 1907, named it *interrogans* because it was shaped like a question mark.

Pathogenic *Leptospira* organisms infect humans through intact mucous membranes or disrupted skin, invade the bloodstream, and disseminate rapidly to multiple organs. Although the precise mechanism by which *Leptospira* causes disease has not been defined, tissue injury is apparently mediated by direct effects of the bacterium.[1]

Leptospira organisms have a predilection for infecting the liver and kidney, although any tissue can be infected. The organism causes hepatocellular dysfunction, which can lead to jaundice, in most instances without producing necrosis. The bacteria also can cause renal tubular dysfunction resulting in renal failure and hemorrhagic vasculitis. The signs and symptoms of leptospirosis during the initial "septicemic" phase of illness are caused by a direct effect of the organism; inflammation during the second or "immune" phase of the illness is related to antigen-antibody complexes.

Epidemiology

Leptospirosis is a zoonosis,[2] and infection with *Leptospira* is widespread in both wild and domestic animals throughout the world.[3] Humans, who are incidental hosts, rarely transmit the organism to other humans or to animals and are unimportant in the maintenance of *Leptospira* in nature; concentrations of bacteria in the urine of infected humans are not sufficient to lead to transmission of the organism. By contrast, *Leptospira* can be shed in the urine of wild animals such as rodents (particularly mice and rats) and by domestic animals such as dogs, cows, and pigs for long periods. Such animals serve as reservoirs for the organism and, because of their close association with people, are the sources of most human infections.

The epidemiology of human leptospirosis largely is determined by the nature of the contact between humans and infected animals and the level of sanitation in the community. In the United States, most cases are reported from the southern states, which may reflect high year-round potential for exposure.[4] In developing countries, rats are the primary reservoir for leptospirosis. In the US, dogs and farm animals are important reservoirs in addition to rats.[4] However, *Leptospira* organisms also have been identified in many wild mammals such as raccoons, foxes, skunks, opossums, and wolves.[4] Although any animal can be infected with any serovar of *Leptospira,* certain serovars seem to infect certain species preferentially. For example, *L. interrogans* serovar *pomona* is isolated most frequently from cows and pigs, serovar *canicola* from dogs, and serovar *icterohaemorrhagiae* from rats and mice. The prevalence of infection in certain animal species is high. Up to 90% of Norway rats have been found to be infected with *L. interrogans;* once infection is established in rats, *L. interrogans* is shed for life. Many other animals, such as dogs (even those immunized), cattle, and pigs, can shed high concentrations of *Leptospira* in urine for months after the initial infection, but shedding diminishes substantially or halts within 6 to 12 months. Organisms survive for 3 months or more in neutral or slightly alkaline water but not in acidic environments.

Infection in humans often occurs through contact with the urine of infected animals, either directly or by contaminated water or soil; human infection also can occur through contact with organs of infected animals. People with occupational, recreational, or accidental contact have an increased risk of leptospirosis. In a case-control study conducted in France, skin lesions, canoeing, contact with wild rodents, and residing in the country were independently associated with leptospirosis, findings showing that leisure activity is an important risk factor for this illness.[5] Dogs have been implicated as a major source of cases in the US.[4] People who live or work on dairy, cattle, or pig farms, as well as abattoir (slaughterhouse) workers and veterinarians, are at increased risk. Field workers, even in developed countries, also may have increased risk of leptospirosis.[6]

The incidence of leptospirosis is unknown because most cases either are asymptomatic or are diagnosed incorrectly. The diagnosis is made most often in teenage boys and young men, presumably because their activities expose them more frequently to the urine of infected animals. However, infection can occur regardless of age or sex.[4–7] Children usually become infected by exposure to stagnant, contaminated water. Common-source outbreaks have occurred after swimming in contaminated ponds.[8] Outbreaks also have occurred in athletes who participated in triathlons.[9]

Clinical Manifestations

The incubation period is approximately 10 days (usual range, 7–14 days), although incubation can be as short as 2 days and as long as 25 days. Clinical manifestations are divided into the initial "septicemic" phase and the subsequent "immune" phase.[10–13] The severity of illness ranges from the classic, icteric Weil syndrome (which affects ~10% of patients) to the more common, less severe anicteric form of leptospirosis.[10–13] The correlations among fever, other clinical findings, and the presence of organisms in body fluids in the different stages of disease are shown in Fig. 184.1.

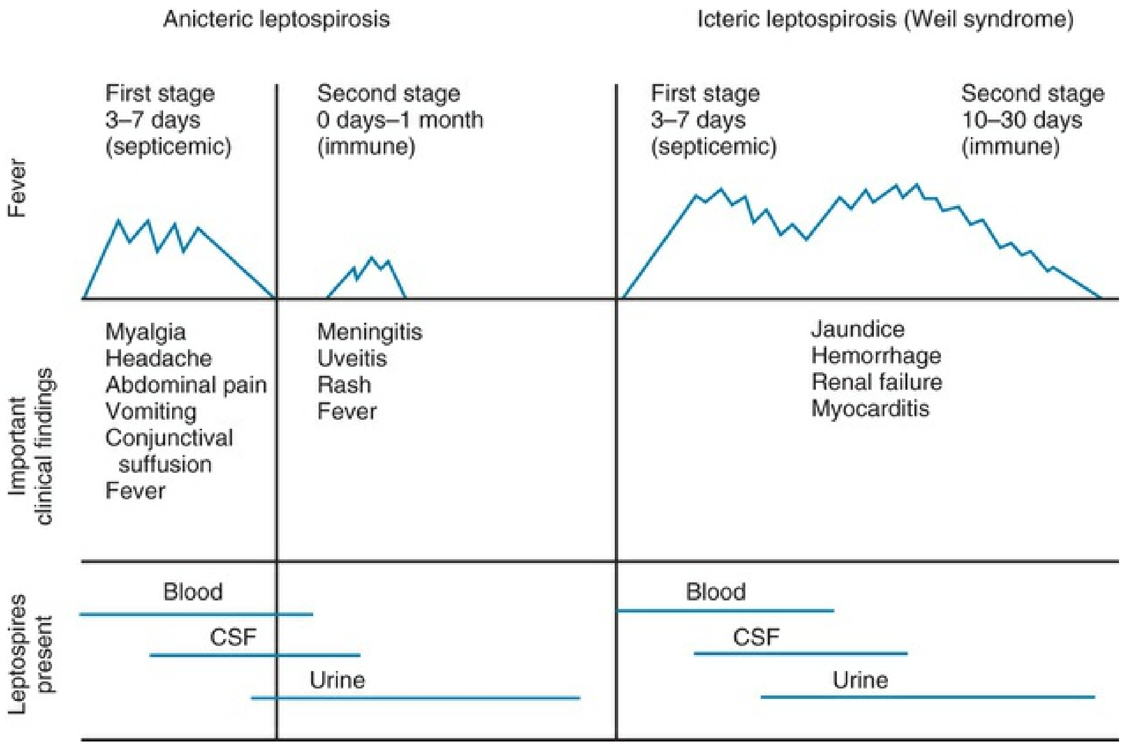

FIGURE 184.1 **Stages of anicteric and icteric leptospirosis. Correlation between clinical findings and the presence of leptospires in body fluids. CSF, cerebrospinal fluid.** (Redrawn from Feigin RD, Anderson DC. Human leptospirosis. CRC Crit Rev Clin Lab Sci 1975;5:413–467.)

Anicteric Leptospirosis

Symptoms of leptospirosis begin abruptly, with virus-like illness marked by fever, headache, and myalgia. Abdominal pain, vomiting, diarrhea, anorexia, and conjunctival suffusion can be present. Rarely, circulatory collapse ensues. During this phase of illness, organisms are present in the bloodstream and cerebrospinal fluid. The severity of illness varies substantially during this phase; symptoms usually last 4 to 7 days and resolve spontaneously.

Some patients have a second, immunologic phase of the illness that begins 1 to 3 days later with low-grade or no fever. During this phase, headache, myalgia, rash, conjunctival suffusion, and hepatomegaly are typical. Nausea, vomiting, and abdominal pain also are common. Typically, headache is severe and can be associated with nuchal rigidity. These manifestations of aseptic meningitis usually last for several days, but they can persist occasionally for 2 to 3 weeks. Other much less frequent manifestations of immune-mediated nervous system disease include encephalitis, Guillain-Barré syndrome, radiculomyelitis, and mononeuropathy or polyneuropathy of the cranial or peripheral nerves.

Interstitial nephritis also is common; manifestations range from incidental pyuria, hematuria, and proteinuria to renal failure. Patients can have right upper quadrant abdominal pain and a mass from acalculous cholecystitis with hydrops of the gallbladder. Pulmonary involvement also can occur. The rash of leptospirosis is immune mediated and nonspecific and can be macular, maculopapular, urticarial, petechial, or purpuric. The infectious and immune phases of anicteric leptospirosis usually resolve within 2 weeks of the onset of symptoms.

Icteric Leptospirosis (Weil Syndrome)

The severe, icteric form of leptospirosis, also called Weil syndrome, can be caused by multiple serovars of *Leptospira.* In the early phase it can be indistinguishable from the benign, anicteric form of leptospirosis, but ultimately it has a mortality rate of 5% to 10%. The hallmarks of Weil syndrome (jaundice, azotemia, and hemorrhage) become apparent 4 to 6 days after the onset of symptoms and can progress through the second week of the illness. Persistent fever (lasting up to 2–3 weeks) and the severity of the illness obscure the biphasic characteristics of the symptoms. Acute (often fatal) pulmonary hemorrhage is one of the most catastrophic manifestations of severe leptospirosis.

Although hepatomegaly, hepatocellular injury, and jaundice are prominent features of Weil syndrome, necrosis and frank hepatic failure do not occur, and survivors have no residual hepatic damage. By contrast, renal impairment, which occurs to a varying degree in both forms of leptospirosis, can be profound in patients with Weil syndrome.[11–14] Bacterially mediated toxicity to the renal tubules can be aggravated by shock and, rarely, by hemoglobinemia from hemolysis and leads to acute tubular necrosis and renal failure. Because of advances in supportive care, the survival rate has improved substantially in recent years. Renal dysfunction is reversible in most but not all cases.

Significant cardiac dysfunction is rare, although many patients have nonspecific electrocardiographic abnormalities (e.g., first-degree heart block) during the first week of the illness. Rarely, congestive heart failure and cardiovascular collapse develop in patients with Weil syndrome.

Laboratory Findings and Diagnosis

Many different laboratory abnormalities are present in patients with leptospirosis, depending on the severity and phase of the illness and the organ systems involved. None is specific. Weil syndrome is associated with leukocytosis and neutrophilia, especially during the early phase of the illness. Anemia is unusual in anicteric leptospirosis but can be severe in Weil syndrome. Serum concentrations of hepatic enzymes, creatinine, and blood urea nitrogen usually are elevated modestly (if at all) in patients with anicteric leptospirosis, but they can be extremely elevated in Weil syndrome. Approximately one half of patients with leptospirosis have clinical signs of meningitis during the immune phase of the illness, and three fourths have cerebrospinal fluid pleocytosis; neutrophils predominate very early in the illness, but a change to mononuclear cells occurs rapidly; protein concentration is normal or elevated; the glucose concentration usually is normal. In the early phase of the illness, the urine usually contains protein, red and white blood cells, and cellular casts.

The number of conditions that could be included in the differential diagnosis of leptospirosis is myriad. Most often, leptospirosis must be differentiated from viral illness and other causes of aseptic meningitis or meningoencephalitis. Leptospirosis can mimic Kawasaki disease, other causes of hepatitis, acute tubular necrosis, interstitial nephritis, and hepatorenal syndrome.

The diagnosis is confirmed by recovery of *Leptospira* from fluid or tissue or by a fourfold or greater rise in antileptospiral antibodies by the microscopic agglutination test in acute and convalescent sera in a patient with a compatible clinical illness. A presumptive diagnosis of leptospirosis can be made in a patient who has a clinically compatible illness and either a titer of antileptospiral antibodies of ≥1 : 100 by the microscopic agglutination test or a positive macroscopic agglutination test result. *Leptospira* organisms cannot be visualized with routine light microscopy; they can be seen by the use of modified silver stains on tissue or fluorescent antibody techniques on urine or tissue specimens. Rarely, *Leptospira* can be visualized by darkfield microscopy when the density of organisms is high.

Culture

Leptospira can be isolated from blood or cerebrospinal fluid during the septicemic phase, and from urine during the immune phase, of leptospirosis. Special media are required and include Tween 80-albumin ([polysorbate 80 with albumin] Sigma-Aldrich, St. Louis, Mo.), Fletcher, and Ellinghausen-McCullough-Johnson-Harris semisolid media; Tween 80-albumin is available commercially and may be superior. Solid media are less reliable for primary isolation of organisms but are useful for secondary isolation of *Leptospira* from semisolid media contaminated with other organisms. Because of difficulty of isolating *Leptospira* and inexperience in clinical microbiology laboratories, specimens for culture from suspected cases should be sent to the National Leptospirosis Laboratory at the Centers for Disease Control and Prevention. Newer molecular diagnostic techniques, such as loop-mediated isothermal amplification and real-time polymerase chain reaction, are promising modalities likely to be substantially more sensitive than currently available serologic and culture methods, but they are not widely available.[15,16] Next-generation sequencing was used to diagnose a case of neuroleptospirosis in an immunocompromised child.[17]

Serology

The macroscopic slide agglutination test is the most useful test for rapid screening.[18,19] Twelve serotypes of killed *Leptospira* (including strains responsible for most infections in the US) are included in this test. The microscopic agglutination test uses live organisms and is the gold standard for detecting antibodies to *Leptospira.*

Generally, agglutination test results are not positive until after the first week of infection; antibody levels peak 3 to 4 weeks after the onset of symptoms and can persist for years, although concentrations may decline over time. Demonstration of at least a fourfold rise in antibodies between acute and convalescent serum samples tested together is most definitive. Newer serologic tests may become useful and include indirect hemagglutination tests, passive microcapsule agglutination test, and enzyme immunoassays.[20–24]

Treatment

Leptospirosis generally is self-limited. Treatment, even if begun late in the course of a relatively severe infection, however, potentially is beneficial. This positive effect of treatment is based on limited data from clinical trials,[25,26] in vitro susceptibility of *Leptospira,* the efficacy of antimicrobial treatment of experimental leptospirosis in animal models (when treatment is begun early), and numerous case reports.[27] An open-label randomized clinical trial conducted in Thailand found that for treatment of patients with severe leptospirosis, penicillin G, cefotaxime, and doxycycline all were highly efficacious.[28] Frequent occurrence of a Jarisch-Herxheimer reaction also supports an effect of treatment.[29]

Treatment should begin as early in the course of the illness as possible. Aqueous penicillin G (200,000–250,000 U/kg/day in divided doses administered every 4 to 6 hours; maximal dose, 12 million U/day) is recommended for serious infection. Ceftriaxone (50 mg/kg up to 1 g/day) is a satisfactory alternative. Less seriously ill patients can be treated with doxycycline orally (2 mg/kg/day divided into 2 doses with maximum of 100 mg twice a day) or amoxicillin (50 mg/kg/day in divided doses 3 times a day; maximum of 500 mg per dose). Therapy is continued for 7 to 14 days. Azithromycin (20 mg/kg, up to 1 g in a single dose the first day followed by 10 mg/kg, up to 500 mg/dose once a day for 2 days) is a satisfactory alternative regimen.

Special Considerations

Congenital Leptospirosis

Although leptospirosis commonly causes abortion in pregnant animals, little information is available on the effect of leptospirosis on the human fetus. The limited information is primarily derived from pregnant women with relatively severe disease. A review of 16 reported cases of leptospirosis during pregnancy revealed that 5 of 8 women (63%) who aborted had leptospirosis during the first or second trimester.[30] Four of the 16 infants were born with evidence of congenital infection (hepatosplenomegaly), 3 were treated successfully, and 1 who died on the second day of life had leptospires seen on stained tissue specimens from the liver and kidneys. Three women with untreated anicteric leptospirosis late in the third trimester gave birth to children who were not infected. No congenital malformations were observed.

Pregnant women in whom leptospirosis develops should be treated promptly with penicillin or ampicillin administered intravenously. At the time of delivery, infants should be examined carefully, and if signs of congenital leptospirosis (jaundice, hepatomegaly) are present, these neonates should be treated promptly with parenterally administered penicillin. Rare cases of leptospirosis from breastfeeding have been described.

Prevention

Widespread infection with *Leptospira* in animals precludes elimination of leptospirosis. Good sanitation reduces the population of the rodent reservoir. Immunization of domestic animals reduces the risk of disease and decreases but does not eliminate leptospiruria.[31] People with occupational exposure to *Leptospira* should take precautions (e.g., wearing gloves), especially when in direct contact with potentially infected fluid, water, soil, or organs of animals. Children should not swim in potentially contaminated ponds; pools should be chlorinated adequately. Doxycycline (200 mg, once weekly) administered to soldiers in Panama reduced the risk of leptospirosis; prophylaxis could be considered in extraordinary circumstances for travelers who are expected to be at risk for a limited time.[32]

Borrelia burgdorferi (Lyme Disease)

Eugene D. Shapiro

Pathogenesis and Immunity

Lyme disease is caused by the spirochete *Borrelia burgdorferi,*[1–3] a cylindrical, fastidious, microaerophilic bacterium that replicates very slowly and requires special medium for in vitro growth. Its cell membrane is covered by flagella and a loosely associated outer membrane. The 3 major outer surface proteins, OspA, OspB, and OspC (which are highly charged basic proteins with molecular weights of ~31, 34, and 23 kd, respectively), as well as the 41-kd flagellar protein, are important targets for the immune response of humans. Biologic differences in strains of *B. burgdorferi* sensu lato presumably are responsible for differences in the clinical manifestations of Lyme borreliosis in Europe and in the United States. *B. burgdorferi* sensu stricto is the only genomospecies that causes disease in the US (with the exception of a recently discovered species, *B. mayonii,* which appears to be a rare cause of Lyme disease in the upper Midwest[3a]), whereas considerable variation exists in the genomospecies, which also include *B. garinii, B. afzelli,* and several others, that cause disease in Europe.[4] The greater frequency of radiculoneuritis in Europe and of arthritis in the US likely is related to these differences.

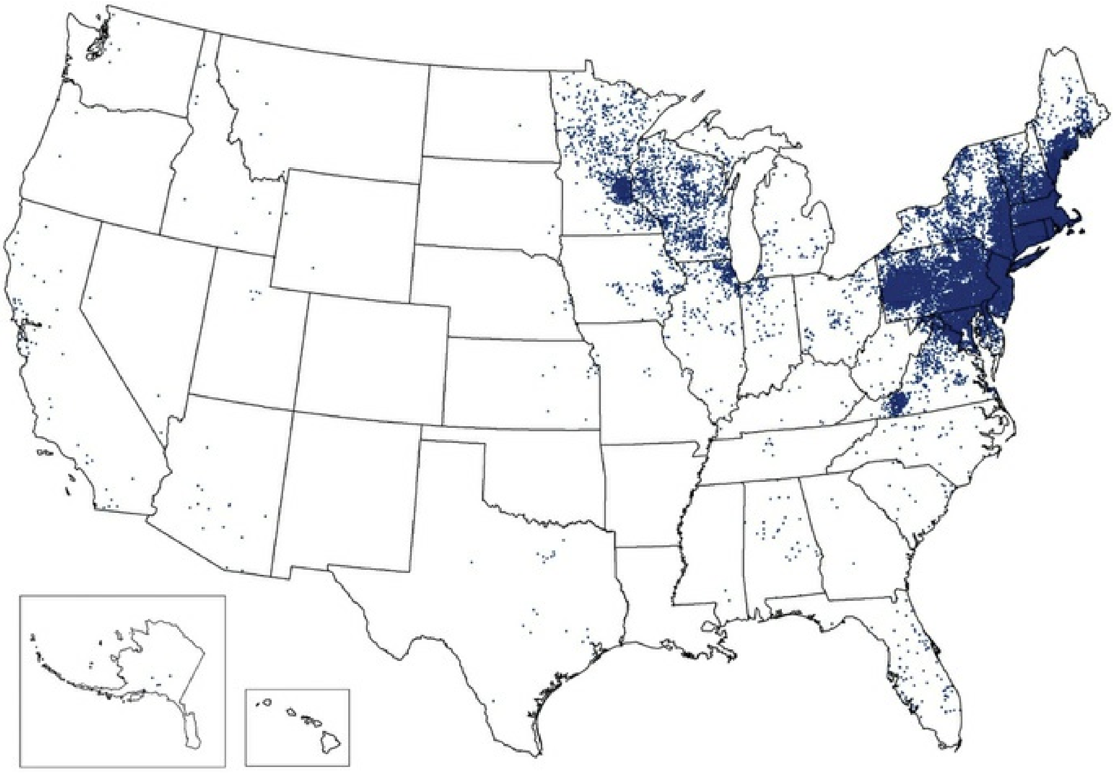
Lyme disease is a zoonosis with complex pathogenesis.[3] *B. burgdorferi* is inoculated by the tick into the skin and begins to spread locally. Local inflammation results in erythema migrans in most patients with symptomatic infection (~90%). Days to weeks later, the spirochete can disseminate, through the bloodstream, to many other sites, including eye, muscle, bone, synovial tissue, central nervous system, and heart. Despite the low density of organisms and the fastidious nature of growth in vitro, *B. burgdorferi* has been isolated from blood or from affected tissues at all stages of illness. Relatively few organisms invade. Host mediators amplify the inflammatory response and cause much of the tissue damage. Preferring cell surfaces, the spirochete can adhere to many different cell types, a feature that may explain clinical manifestations of involvement in a broad array of organ systems. Because the organism can persist in tissues for prolonged periods when untreated, symptoms can appear months after infection. The host's immune response is an important element in the pathogenesis of Lyme disease.[4] Symptoms of early localized disease, early disseminated disease, and late disease usually are caused by inflammation as a direct result of the spirochete's presence (it does not produce toxins). Some people with Lyme disease who are treated early in the course of infection do not develop antibodies and remain susceptible to subsequent infections. However, evidence indicates that serotype-specific (as opposed to species-specific) immunity can develop after a single episode of erythema migrans[5]; a second case of erythema migrans virtually always results from a strain different from the one that caused the initial case of erythema migrans.[6] People with late Lyme disease rarely develop erythema migrans again, even with repeated exposure to ixodid ticks in endemic areas, a finding suggesting that these people have developed immunity.

Epidemiology

Disease in Humans

Although Lyme disease occurs throughout the world, endemicity varies widely. In the US, from 1992 to 2013 >90% of reported cases came from 10 states.[7] Most cases occur in southern New England and in the eastern Mid-Atlantic states; fewer cases occur in Minnesota and Wisconsin. Rarely, cases occur along the northern

Pacific coast (Fig. 185.1).[7] In Europe, most cases occur in the Scandinavian countries and in central Europe, although the disease occurs throughout the region.



1 dot placed randomly within county of residence for each confirmed case

FIGURE 185.1 **Reported cases of Lyme disease: 2013.** (From Centers for Disease Control and Prevention. Lyme Disease: Data and Statistics. http://www.cdc.gov/lyme/stats/.)

Although frequency has increased and the geographic distribution of Lyme disease in the US has expanded, the incidence of Lyme disease varies substantially from region to region and within local areas.[1–3,7] The annual number of reported cases in the US increased from 9908 cases in 1992 to 27,203 cases in 2013.[7] This change likely reflects both the increased incidence and the improved recognition and reporting of disease. Estimates of the incidence of disease are complicated by reliance on passive reporting of cases as well as by the high frequency of misdiagnosis of disease. Furthermore, seroepidemiologic studies indicate that some patients who have evidence of recent infection with *B. burgdorferi* are asymptomatic.[8,9] The reported annual incidence in the most highly endemic areas, such as Connecticut, is approximately 75 cases per 100,000 persons, although in certain localized areas in which the disease is hyperendemic (e.g., Lyme, Conn.), the annual incidence can be as high as 1000 or more per 100,000 persons. The reported incidence is highest among children 5 to 14 years old. Most cases occur during the summer months.

Ecology

Lyme disease is a zoonosis.[3,10] *B. burgdorferi* is transmitted by ticks of the *Ixodes* genus. In the US, vectors are *I. scapularis* (the black-legged tick, also called the deer tick) in both the Northeast and Midwest and *I. pacificus* (the Western black-legged tick) in the Pacific states. The life cycle of these ticks consists of 3 stages (larva, nymph, and adult) that develop during a 2-year period. Larvae are not infected with *B. burgdorferi*. Ticks become infected as they feed on infected small mammals, such as *Peromyscus leucopus* (the white-footed mouse), which are natural reservoirs for the bacteria. Deer are important hosts for adult ticks but are not a competent reservoir for *B. burgdorferi*.

Multiple factors affect the risk of transmission of *B. burgdorferi* from ticks to humans. The first is the likelihood that a tick is infected. The proportion of infected ticks varies tremendously by geography as well as by species and stage of life cycle. Most cases of Lyme disease are transmitted by nymphal deer ticks because they outnumber adult ticks, are active during times of the year when many more people are outdoors, and are very small and therefore less likely to be detected and removed before transmitting infection. *I. pacificus* often feeds on lizards, which are not a competent reservoir for *B. burgdorferi;* lizard blood contains factors that kill the bacteria. Consequently, fewer than 10% of these ticks are infected with *B. burgdorferi.* By contrast, *I. scapularis* feeds on small mammals that constitute the natural reservoir for *B. burgdorferi.* In southeastern Connecticut and in Westchester County, New York, which have very high incidences of Lyme disease, rates of infection for *I. scapularis* are 0% for larvae, 15% to 25% for nymphs, and 30% to 50% for adults.

Clinical Manifestations

Lyme disease generally is divided into 3 clinical stages: early localized disease, early disseminated disease, and late disease.[1–4] Box 185.1 shows the major clinical features of these stages.

Box 185.1

Clinical Manifestations of Lyme Disease in Children According to Stage of the Disease

Early Localized Disease (3–32 Days After Tick Bite)

- Erythema migrans (single), sometimes accompanied by any of the following nonspecific symptoms or signs:
    - Myalgia
    - Headache
    - Fatigue
    - Fever
    - Lymphadenopathy (regional or generalized)

Early Disseminated Disease (3–10 Weeks After Tick Bite)

- Erythema migrans (multiple)
- Cranial neuritis (especially facial palsy)
- Meningitis
- Carditis (especially heart block)
- Radiculoneuritis

All of the above can be accompanied by any of the following nonspecific symptoms or signs:

- Myalgia
- Headache

- Fatigue
- Fever
- Lymphadenopathy (regional or generalized)
- Conjunctivitis
- Neck pain and stiffness

Late Disseminated Disease (2–12 Months After Tick Bite)

- Arthritis (usually monoarticular or pauciarticular with involvement of the knee)

Early Localized Disease

The first clinical manifestation of Lyme disease is a typical annular rash, erythema migrans (Fig. 185.2).[2] Approximately two thirds of children with symptomatic infection have a single erythema migrans lesion, which occurs at the site of the tick bite (although typically the bite was not recognized).[11] Onset of rash is usually 7 to 14 days after the bite (range, 3–32 days). The rash most often is uniformly erythematous, but it can appear as a target lesion with central clearing. Occasionally it can have a vesicular or necrotic center. The rash can be pruritic, painful, or asymptomatic. Associated systemic symptoms (e.g., fever, myalgia, headache, and malaise) are variably present.[2] Untreated, the rash gradually expands (hence the name *migrans*) to an average diameter of 15 cm (although lesions >30 cm can occur) and persists for 1 to 4 weeks. Lesions can occur anywhere on the body, although they are more common in the head and neck area in children than in adults.

FIGURE 185.2 (A) Typical expanding annular lesion of erythema migrans at the site of a tick bite. The central area underwent minor necrosis. (B, C) A 5-year-old boy had a giant expanding lesion of erythema migrans with central clearing on (B) his back and another on (C) his face, probably from bacteremic dissemination. (A, Courtesy of J. Capra, Abilene, Tex.; B and C, Courtesy of M. Weir, Temple, Tex.)

Early Disseminated Disease

The likelihood of dissemination is related to strain-specific characteristics of the bacteria.[12] Approximately one fourth of children with Lyme disease initially receive a diagnosis of early disseminated infection when, as a consequence of bacteremic dissemination to multiple sites, secondary erythema migrans lesions develop days or weeks after initial infection[11] (Fig. 185.3). Secondary lesions usually are smaller than the primary lesion and often are accompanied by fever, myalgia, headache, and fatigue; conjunctivitis and lymphadenopathy also can develop. Meningitis with clinical evidence of meningeal irritation (e.g., nuchal rigidity accompanied by a headache) is the presentation in approximately 2% of patients. Carditis, usually marked by varying degrees of heart block, can occur at this stage, but complete heart block is rare

(<1% of patients). Rare instances of sudden death secondary to Lyme carditis have been reported.[13]

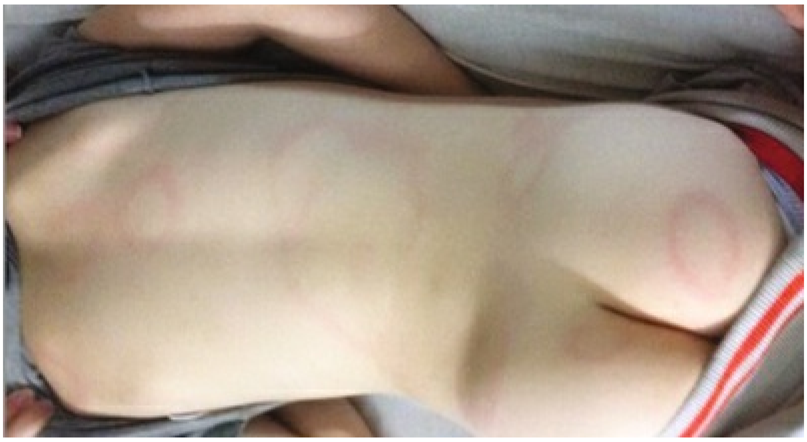

FIGURE 185.3 **Multiple erythema migrans lesions.**

Focal neurologic involvement, in particular cranioneuropathy, is a manifestation of early disseminated infection. The most common sign, paralysis of the facial (seventh cranial) nerve, is relatively common in children (3%–5% of cases) and can be the only manifestation of Lyme disease. Palsy usually lasts from 2 to 8 weeks and resolves completely. Rarely, palsy resolves partially or not at all. No evidence indicates that the clinical course of facial palsy is affected by antimicrobial therapy. Radiculoneuritis, manifested as radicular pain with motor and sensory abnormalities of peripheral nerves, has been reported in children in the US, although it is more common among adults and in Europe.

Late Disease

Arthritis, the usual manifestation of late Lyme disease, is the presenting complaint in approximately 7% of children with Lyme disease. Large joints are affected primarily, and the knee is involved in more than 90% of cases. Characteristically, the affected joint is swollen and tender, and it has an effusion, although pain and limitation of motion usually are modest and are less marked than in other bacterial arthritides. With treatment, the primary episode of arthritis usually abates over 4 to 7 days, with complete resolution over 2 to 6 weeks. Arthritis recurs or persists in 10% to 20% of treated patients and usually resolves with retreatment. In virtually all untreated patients, arthritis recurs, often in other joints, but signs and symptoms eventually resolve even without treatment.[14] Baker cyst is a well-described complication of Lyme arthritis and can occur unilaterally or bilaterally, with or without frank arthritis, and before, during, or after therapy (Fig. 185.4).[15,16] Immune-mediated chronic arthritis associated with Lyme disease (sometimes called antibiotic-refractory Lyme arthritis) is rare in adults and is extremely rare in children. Some controversy exists about whether this is caused by an autoimmune process or by delayed clearance of borrelial antigens from killed bacteria.[17–19] Late manifestations of Lyme disease of the central nervous system have been reported only rarely in children.

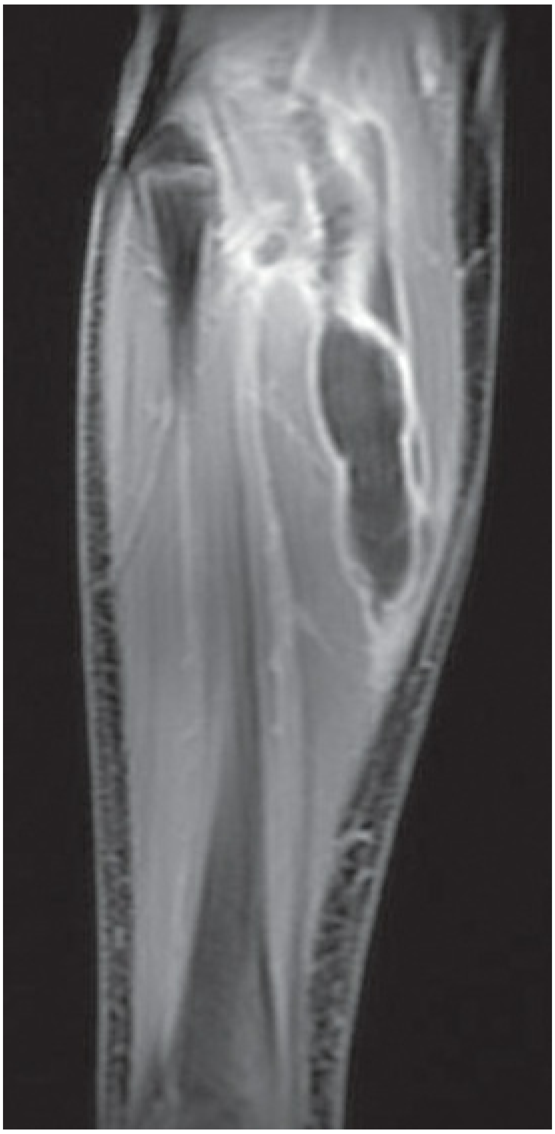

FIGURE 185.4 A 12-year-old boy came to attention after 2 weeks of pain and swelling in his knee and then

in his calf, which was warm, swollen, and tender. Fat-suppressed T1-weighted coronal magnetic resonance imaging with contrast shows an enhancing, multilobulated, fluid-filled mass (Baker cyst) with atypical inferior extension. Fluid had 140,000 white blood cells/mm^3 and was sterile. Serum Lyme antibody was 13 EU/mL. (Case courtesy of S. S. Long.)

Laboratory Findings and Diagnosis

Except for erythema migrans, the clinical manifestations of Lyme disease are nonspecific. Erythema migrans can be confused with several other skin lesions (ringworm, nummular eczema, cellulitis, granuloma annulare, and insect bites), but its rapid and continuing expansion is distinctive. Lyme meningitis (with lymphocytic pleocytosis) tends to have a slower onset and to be more prolonged than typical aseptic meningitis caused by enteroviruses, and papilledema and increased intracranial pressure often occur.[20] Lyme arthritis usually is subacute in onset, with effusion out of proportion to pain or disability, but sometimes it can mimic acute pyogenic arthritis.

Routine laboratory tests rarely aid the diagnosis of Lyme disease because most laboratory abnormalities also are nonspecific. Not uncommonly, mild cerebrospinal fluid pleocytosis can be found in patients with facial nerve palsy despite the absence of clinical manifestations of meningitis.[21]

Isolation of *B. burgdorferi* in a specimen from a symptomatic patient is diagnostic of Lyme disease; however, the appropriate medium is expensive, time to isolation can be 4 weeks, and sensitivity of culture is poor because of the low concentration of organisms. In addition, an invasive procedure is required to obtain appropriate material for culture. Diagnostic tests based on the identification of DNA of *B. burgdorferi,* including the polymerase chain reaction, also generally have poor sensitivity in addition to the substantial risk of a false-positive result because of contamination. Consequently, laboratory diagnosis of Lyme disease usually rests on detection of antibodies to *B. burgdorferi.*[22]

Typical antibody responses to acute infection with *B. burgdorferi* are well described. Specific immunoglobulin (Ig) M antibody appears 3 to 4 weeks after infection begins, peaks by 6 to 8 weeks, and subsequently declines. However, prolonged (years) elevation of IgM antibodies despite clinical cure is not unusual.[23] Specific IgG antibody usually appears 4 to 8 weeks after onset of infection, peaks 3 to 6 months later, and can remain elevated indefinitely after cure of infection.[22–24] Effective antimicrobial therapy may or may not be associated with a decline in specific IgG or IgM antibody level.[23,24]

Enzyme immunoassay (EIA) is the most widely used procedure for the detection of antibodies against *B. burgdorferi.* The procedure is associated with false-positive results because of cross-reactive antibodies in patients with other spirochetal infections (e.g., syphilis, leptospirosis, or relapsing fever), certain viral infections (e.g., varicella), or certain autoimmune diseases (e.g., systemic lupus erythematosus), or from antibodies that cross-react with spirochetes of normal oral flora. The immunoblot test (Western blot) is used to detect serum antibodies against specific proteins of *B. burgdorferi.* Because many uninfected patients have antibodies against certain proteins of *B. burgdorferi* (especially against the 41-kd flagellar protein), guidelines have been established for diagnosing Lyme disease with the immunoblot test.[22,25] Currently, a 2-tier approach to diagnose Lyme disease is recommended, beginning with a sensitive EIA; if that result is either positive or equivocal, then a Western blot is used to validate the result.[25] Western blot tests should be performed only in conjunction with a positive or equivocal EIA or other quantitative test result. A 1-step EIA assay (VIsE C6) for IgG antibody to the variable major protein-like sequence-expressed lipoprotein (VlsE) sixth invariant region (C6) has good sensitivity but is somewhat less specific than the 2-step approach for determining the presence of specific antibody.[26]

Antibody test results often are negative in patients with early infection, such as patients with a single erythema migrans lesion.[2] People with disseminated or late Lyme disease virtually always have a strong IgG response to *B. burgdorferi.* Antibody response can be abrogated if invading organisms are killed when patients are treated early in the course of erythema migrans.

The interpretation of serologic test results for Lyme disease has multiple pitfalls. Some commercial laboratories are performing tests for Lyme disease by using assays for which accuracy and clinical usefulness have not been established.[27] Serologic tests performed in several reference laboratories throughout the US are relatively accurate, with good sensitivity and specificity. However, the predictive value of a positive result, even of a Western blot, depends primarily on the pretest likelihood (on the basis of the clinical and epidemiologic history and the results of the physical examination) that the patient's problem is caused by Lyme disease. Although nonspecific, subjective symptoms such as fatigue, arthralgia, or headache can accompany Lyme disease, such widely prevalent symptoms alone, in the absence of a specific objective sign of infection such as erythema migrans, facial nerve palsy, or arthritis, hardly ever signify Lyme disease. Positive antibody test results in such patients almost always are false-positive results.[28,29] Such nonspecific symptoms can have a variety of causes, including fibromyalgia or medically unexplained symptoms.[30,31]

Serologic tests for Lyme disease, even those performed by reference laboratories, should be performed selectively to confirm specific clinical findings suggestive of Lyme disease. A positive serologic test result does not necessarily denote active infection. It can reflect previous asymptomatic infection or previously cured clinical infection.[22–24] Test results generally cannot be used to assess either activity or relapse of past infection.

Treatment and Outcomes

Antimicrobial treatment of Lyme disease is highly effective; expert guidelines for management are published.[32] Box 185.2 lists the recommended therapy for children with Lyme disease. Although children younger than 8 years of age are not treated with doxycycline because of concern that it may permanently discolor teeth, growing evidence indicates that such concern may not be justified.[33] Patients who are treated with doxycycline should be alerted to the risk of drug-related, sun-induced dermatitis.

Box 185.2

Antimicrobial Treatment of Lyme Borreliosis

Early Disease

- **Erythema migrans and early disseminated disease**

Doxycycline, 4 mg/kg/day divided bid (maximum, 100 mg/dose) for 14 days (range, 10–21 days; see text for children <8 years of age) *or* amoxicillin, 50 mg/kg/day divided tid (maximum, 500 mg/dose) for 14 days (range, 10–21 days)

Alternative agent for patients who cannot take either amoxicillin or doxycycline: cefuroxime axetil (preferred), 30–50 mg/kg/day divided bid (maximum, 500 mg/dose) *or* erythromycin, 50 mg/kg/day divided qid (maximum, 250 mg/dose) *or* clarithromycin, 15 mg/kg/day divided bid (maximum, 500 mg/dose), all for same duration as above, *or* azithromycin, 10 mg/kg/day (maximum, 500 mg/dose) in a single daily dose for 7–10 days

- **Seventh nerve palsy or palsy of other cranial nerves**

Treat as for erythema migrans for 14–21 days (doxycycline preferred if possible); do not use corticosteroids

- **Carditis**

First- or second-degree heart block: same treatment as for erythema migrans

Third-degree heart block: treat as for meningitis

- **Meningitis**[a]

Ceftriaxone, 75–100 mg/kg/day in a single daily dose (maximum, 2 g) for 14 days (range, 14–28 days administered IV or IM) *or* cefotaxime, 150–200 mg/kg/day (maximum, 6 g/day) divided q8h administered IV for 14 days (range, 14–28 days) *or* penicillin G, 200,000–400,000 U/kg/day (maximum, 20 million U/day) divided q4h administered IV for 14–28 days

Late Disease

- **Central or peripheral nervous system**[b]

Same as for meningitis

- **Arthritis**

Initial treatment is the same as for erythema migrans, except treatment should be given for 28 days; if swelling fails to resolve after 2 months or if the patient has a recurrence, consider a second course of oral therapy, or use parenteral therapy and treat as for meningitis

bid, twice daily; IM, intramuscularly; IV, intravenously; qid, 4 times daily; tid, 3 times daily.

---

[a] Evidence indicates that oral doxycycline is as effective as intravenous ceftriaxone to treat Lyme meningitis.[57]

[b] For isolated palsy of the facial nerve or other cranial nerves, see under Early Disease.

From Wormser GP, Nadelman RB, Dattwyler RJ, et al. Infectious Diseases Society of America practice guidelines for the treatment of Lyme Disease, human granulocytic anaplasmosis, and babesiosis. Clin Infect Dis 2006;43:1089–1134. (http://www.idsociety.org/uploadedfiles/idsa/guidelines-patient_care/pdf_library/lyme%20disease.pdf)

Some patients experience a Jarisch-Herxheimer reaction within 48 hours after treatment; this reaction results from bacteriolysis and release of cellular products. Symptoms of fever, sweating, and myalgia resolve spontaneously within 1 to 3 days. Treatment with nonsteroidal anti-inflammatory agents can be useful in treating a Jarisch-Herxheimer reaction as well as myalgia, arthralgia, headache, and other symptoms of Lyme disease; the duration of anti-inflammatory therapy is determined empirically.

Cefuroxime is preferable to a macrolide antibiotic as an alternative for patients for whom both doxycycline and amoxicillin are contraindicated. Little need exists for new agents because the results of treatment with standard therapy (e.g., amoxicillin or doxycycline) have been excellent.[11,32] Reinfection after treatment can occur after localized erythema migrans, but it is rare after either early disseminated or late Lyme disease. Clinicians also should keep in mind the possibility of coinfection with other pathogens (*Babesia microti* or *Anaplasma phagocytophilum*) that are also transmitted by *Ixodes* ticks.

A substantial body of literature indicates that the outcomes for people with Lyme disease who receive conventional antimicrobial treatment are excellent.[2,32,34–39] The most common reason for “failure” of treatment of Lyme disease is that the diagnosis was erroneous.[28,29,40–43] Although patients with Lyme disease who are successfully treated may have fatigue, arthralgia, or myalgia that resolves over weeks to months after completion of therapy, no evidence indicates that such symptoms are related to persistence of the organism. Repeated courses of antimicrobial agents do not speed the resolution of persistent musculoskeletal pain, neurocognitive symptoms, dysesthesia, or fatigue.[32,43–46] Misinterpretation of the cause of persistent symptoms or of antibody test results, augmented by inaccurate information on the Internet and in the lay press,[47] has led to unfounded anxiety about the longterm consequences of Lyme disease among both the public and physicians.

Special Consideration: Congenital Lyme Disease

Because another spirochete, *Treponema pallidum,* is transmissible transplacentally, concern exists that *B. burgdorferi* could be transmitted from an infected pregnant woman to her fetus. Case reports have documented isolation of *B. burgdorferi* from abortuses and infection in a few live-born infants with congenital anomalies, but placentas, abortuses, and tissue in which the spirochete was identified did not show histologic evidence of inflammation. In addition, no consistent pattern of congenital malformation has been observed, unlike with other diseases caused by intrauterine infections.

Two serosurveys conducted in endemic areas found no difference in the prevalence of congenital malformations among women who were seropositive versus seronegative for *B. burgdorferi.* In the largest study of Lyme disease in pregnancy, investigators prospectively observed 2000 pregnant women in Westchester County, New York, 79 of whom had Lyme disease according to history or serologic test results. Although the number of infected women was relatively small (15 had Lyme disease during the pregnancy), no association was found between maternal exposure to *B. burgdorferi* before conception or during pregnancy and fetal death, prematurity, or congenital malformations.[48] An extensive survey of 162 pediatric neurologists in endemic areas revealed that none had observed a clinically significant neurologic disorder either attributable to congenital Lyme disease or after Lyme disease during pregnancy.[49]

No definite evidence indicates that *B. burgdorferi* causes congenital disease. If congenital Lyme disease exists, it is extremely rare. Pregnant women with Lyme disease should be treated as stage and severity of illness dictate (although doxycycline is contraindicated). Transmission of *B. burgdorferi* through breastfeeding has not been documented.

Prevention

In areas where deer ticks are prevalent, children are commonly bitten. The overall risk of acquiring Lyme disease after a recognized tick bite is approximately 1% to 3% in areas where the disease is highly endemic.[50–52] The risk of becoming infected is greater if the tick is in the nymphal stage and is engorged when discovered (indicating substantial feeding time, which is necessary for transmission of the organism to occur). Treatment of infection, if it develops, is highly effective. Consequently, routine administration of antimicrobial prophylaxis after a deer tick bite is not recommended.[32,52,53] In contrast, in endemic areas of the Northeast or the Upper Midwest in the US, if the tick is reliably identified as either a nymphal or an adult deer tick that is engorged and the child is ≥8 years of age, treatment with a single dose (4 mg/kg up to 200 mg maximum) of doxycycline (administered with food to minimize nausea) may be indicated.[51–53] The routine testing of ticks that have been removed from humans for infection with *B. burgdorferi* also is not recommended because the sensitivity, specificity, and predictive values of the results of such tests on ticks for predicting infection of the human who was bitten are unknown. Hypersensitivity reactions to tick products frequently result in erythematous or nodular lesions <2 cm in diameter that do not expand and should not be misinterpreted as erythema migrans. Topical antimicrobial treatment of a tick bite has successfully prevented dissemination of infection in an animal model but has not been tested in humans.[54]

A reasonable approach to avoiding Lyme disease consists of (1) wearing appropriate protective clothing (e.g., lightweight long pants tucked into socks) when entering tick-infested areas; (2) checking for ticks after spending time in such areas; and (3) removing ticks promptly.[55,56] Insect repellents also may provide temporary protection.

Antibodies against the OspA protein protect against Lyme disease in animal models. A recombinant OspA vaccine was licensed for people 15 to 70 years of age,[9] but it was removed from the market in 2002 by the manufacturer because of poor sales.

Other *Borrelia* Species and *Spirillum minus*

Eugene D. Shapiro

Borrelia Species (Relapsing Fever)

Microbiology

Members of the genus *Borrelia* are microaerophilic spirochetal bacteria characterized morphologically by coarse and irregularly shaped coils, with a cell wall and an inner cytoplasmic membrane, between which are multiple flagella that provide corkscrew-like motility. Substantially thicker than the *Treponema* spp., *Borrelia* spp. stain easily with aniline or acid dyes and can be visualized on light microscopy in Wright- or Giemsa-stained blood smears. Isolation of the organism is difficult, requiring special media, and growth is slow.[1]

Borrelia spp. can change the antigenic structure of their surface proteins by transposition of structural genes on a linear plasmid.[2] This ability allows them temporarily to elude host defenses, thus resulting in "relapsing fever" in infected humans.[3,4] The resolution of symptomatic stages of the illness correlates with peak concentrations of antibodies against specific antigens.[5] Borreliae cause vasculitis, with a predilection for capillaries and small arterioles of any organ, especially the reticuloendothelial system, bone marrow, and central nervous system.

Epidemiology

Ticks and lice are vectors that transmit the bacteria to humans. The epidemiology of the disease is determined by environmental conditions conducive to vectors and, in the case of the ticks, the likelihood of contact with humans.[6] Risk factors, organisms, and vectors associated with each form of disease are shown in Table 186.1.

TABLE 186.1

Causes of *Borrelia* Relapsing Fever

Vector	Bacteria	Risk Factors
LOUSE		
Pediculus humanus	*B. recurrentis*	Crowding, poverty, war, famine
TICK		
Ornithodoros ticks[a] *O. hermsi* *O. parkeri* *O. tholozani* *O. talaje* *Ixodes* ticks *I. scapularis* *I. pacificus* *I. ricinus* *I. persulcatus*	*B. duttoni*[b] *B. hermsii* *B. parkeri* *B. persica* *B. mazzottii* *B. miyamotoi*	Exposure to environments where rodents thrive: old cabins, caves, primitive huts Exposure to areas (e.g., fields, woods, residential yards adjacent to woods) where these ticks are prevalent

[a] These are only some of the many species that are vectors for relapsing fever.

[b] These are only some of the many species that cause relapsing fever.

Louse-borne relapsing fever, caused by *Borrelia recurrentis,* is transmitted by the body louse, *Pediculus humanus.* Crab lice *(Phthirus pubis)* cannot transmit this organism. No animal reservoir for *B. recurrentis* has been found; the existence of this organism depends on human-to-human transmission by lice. Bacteria multiply in the hemolymph of the louse, but infected fluid is not inoculated into humans. Human infection occurs when the louse is crushed (usually inadvertently) and the organisms come in contact with skin or mucous membranes. Infection with *B. recurrentis* is associated with crowding and poor hygiene; epidemics are associated with war, famine, and natural disasters such as earthquakes. A major epidemic of louseborne relapsing fever occurred in Europe during World War II. The disease is endemic in Ethiopia and Sudan. Infection with *B. recurrentis* is virtually unknown in the United States.

Tickborne relapsing fever, caused by several species of *Borrelia,* is transmitted primarily by soft ticks of the genus *Ornithodoros.* Many small animals (chipmunks, rats, mice, squirrels, and others) serve as reservoirs for *Borrelia* spp. and as hosts for *Ornithodoros* ticks. Variable transovarial transmission of bacteria to larval ticks occurs, and an enzootic cycle is well established in certain areas of the US. Ticks thrive in warm, humid environments and at altitudes from 1500 to 6500 feet (450–2000 m).

Unlike hard ixodid ticks that transmit *B. burgdorferi* only after feeding for days, soft ticks feed for less than an hour yet are able to transmit *Borrelia* during this relatively brief period. Transmission occurs by inoculation of saliva from an infected tick. Ticks often feed at night, and the human host rarely is aware of the bite, which can be associated with up to a 50% risk of disease if the tick is infected. Unlike with louseborne recurrent fever, humans are incidental hosts for bacteria that cause tickborne relapsing fever. Humans become infected when they enter environments where the ticks thrive, such as old cabins and caves. Tickborne recurrent fever has a worldwide distribution. The disease is endemic in parts of East Africa, Asia, and South America. Most cases in the US occur in rural areas in the Western states. Outbreaks have occurred among tourists staying in log cabins at Western parks and among spelunkers.[7–9]

A more recently discovered bacterium, *B. miyamotoi*, is the first *Borrelia* species in the relapsing fever group that is transmitted by hard ticks (*Ixodes* species).[10,11] *B. miyamotoi* has been found in all species of *Ixodes* ticks in North America, Europe, and Asia, and apparently it also shares animal reservoirs with *B. burgdorferi.* The full ecology and epidemiology of disease caused by *B. miyamotoi* have not yet been determined. However, *Ixodes* ticks clearly can transmit *B. miyamotoi* without, or with, *B. burgdorferi.*

Clinical Manifestations

Tickborne and louseborne relapsing fevers are indistinguishable from each other clinically (manifestations of infection with *B. miyamotoi* are discussed separately), although louseborne disease tends to have fewer (though more severe) recurrences.[12–17] The exact time of exposure usually is unknown because lice typically cause chronic infestations and the bites of ticks often are unrecognized. Symptoms begin 5 to 10 days after exposure, with sudden onset of fever and chills usually accompanied by headache, myalgia, arthralgia, photophobia, and cough. Common physical findings include petechiae or frank purpura, conjunctivitis, and abdominal tenderness (often with an enlarged and tender liver or spleen). Nuchal rigidity often occurs,[18] and some patients have jaundice, epistaxis, or gastrointestinal hemorrhage. This phase of the illness is associated with bacteremia, usually lasts for 3 to 7 days, and resolves spontaneously.

During the next (crisis) phase, patients are afebrile or have low-grade fever and may have a diffuse maculopapular rash. Diaphoresis, extreme fatigue, and, occasionally, hypotension characterize this phase. Borreliae are not found in the blood but presumably are present in organs such as the spleen and liver, where antigenically variant strains propagate.

The relapse phase of illness, which typically occurs 5 to 7 days after primary spirochetemia resolves, is marked by rapid onset of high fever and chills as well as the other signs and symptoms of the initial spirochetemic phase. In untreated patients, 3 to 5 relapses are typical (although many more are possible) in tickborne infections, and up to 2 or 3 relapses occur in louseborne infections. Relapsing fever usually resolves even if untreated, although deaths have occurred. During some epidemics, mortality rates as high as 20% to 30% have been reported; poor general health and poor nutrition can be responsible. Severe hepatitis, lobar pneumonia, myocarditis, ruptured spleen, and cerebral hemorrhage are rare causes of death. Pregnant women who become infected often have spontaneous abortion, in most instances because of thrombocytopenia and retroplacental hemorrhage. Longterm sequelae are uncommon among survivors, although iridocyclitis can result in scars and impairment of vision.

Although *B. miyamotoi* is classified in the relapsing fever group of *Borrelia*, manifestations of infection may not be the same as those of other tickborne *Borrelia* infections. Although relapsing fever–like illness can occur, prolonged fever, presentations similar to anaplasmosis, and meningoencephalitis in immunocompromised patients have been reported.[11,19–21] Generally, reports are anecdotal and are likely to remain so until better and more widely available diagnostic tests are developed.

Laboratory Findings and Diagnosis

Laboratory abnormalities are nonspecific. Leukocytosis (with a left shift) and a markedly elevated erythrocyte sedimentation rate are typical. Cerebrospinal fluid often is abnormal, usually with 10 to 2000 predominantly mononuclear white blood cells/mm,[3] elevated protein levels, and normal glucose concentrations.

Awareness of epidemiology is crucial to making the diagnosis. Louseborne relapsing fever usually occurs in epidemics at times of unstable social conditions; in these circumstances, the symptoms are rarely confused with those of any other condition except epidemic typhus, which also is transmitted by the body louse. By contrast, except in certain developing countries, tickborne relapsing fever is uncommon and occurs sporadically. For patients with compatible symptoms, a history of recent exposure to old cabins, caves, or other environments where rodents reside should lead to consideration of relapsing fever.

Culture is an insensitive method for confirming the diagnosis, which is best made by examination of peripheral blood during febrile episodes using darkfield microscopy or Wright or Giemsa staining.[22] Diagnostic yield can be enhanced by staining of a smear with acridine orange and use of fluorescence microscopy. Polymerase chain reaction assay is a promising diagnostic test but is not available generally.[23]

Treatment

Tetracycline (500 mg/dose administered 4 times a day) or doxycycline (2 mg/kg/day divided into 2 doses with maximum dose of 100 mg twice a day) are the drugs of choice for relapsing fever.[12,17] Treatment is administered for 7 to 10 days; however, for louseborne relapsing fever, 100 mg of doxycycline or 500 mg of either tetracycline or erythromycin given once orally has been effective.[24–26] In children <8 years of age, erythromycin (30–50 mg/kg/day divided into 4 doses) is preferred, although penicillin also is effective. *B. miyamotoi* appears to be susceptible to doxycycline and to amoxicillin.[11]

If vomiting is severe, the initial dose of the antimicrobial agent can be administered intravenously, although a severe Jarisch-Herxheimer reaction can occur. This reaction, marked by rigors, increased fever, and, in severe cases, hypotension, typically occurs within a few hours after initiation of antimicrobial therapy and cannot be prevented by previous administration of corticosteroid. Nonsteroidal anti-inflammatory medications and, in severe instances, intravenously administered fluids have been used for treatment.

Prevention

The primary means of preventing relapsing fever consists of control and avoidance of vectors that transmit the disease. Ticks that transmit relapsing fever are dispersed widely throughout the world. The use of insecticides around the inner walls of primitive buildings and huts (where ticks often are found) in developing countries has reduced the frequency of disease.[27] Postexposure chemoprophylaxis with 5 days of doxycycline was highly effective in persons thought to be at high risk after a tick bite.[28] The risk of louseborne disease can be controlled through good personal hygiene and prompt treatment if an infestation occurs.

Spirillum Minus (Rat-Bite Fever)

Spirillum minus, a short, spiral bacterium, is a cause of rat-bite fever.[29–33] *S. minus* is more common in Asia than in the US and elsewhere in North America, where most cases of rat-bite fever are caused by *Streptobacillus moniliformis.* In Japan, the disease is known as *sodoku* (*so*, “rat”; *doku*, “poison”).

S. minus is a tightly coiled, gram-negative spiral bacillus. Infection results from inoculation during the bite of a rat. Up to one fourth of rats are colonized with *S. minus* in sputum, conjunctiva, blood, or nasopharynx. Unlike streptobacillary rat-bite fever, *S.*

minus infection has not followed ingestion of the organism. Transmission of infection between humans does not occur.

One to 4 weeks after the bite, patients have abrupt onset of fever, chills, and headache, usually in association with an inflamed, tender, ulcerated wound at the site of the rat bite. Typically, the wound, which had healed previously, ulcerates concurrently with onset of systemic symptoms. Musculoskeletal symptoms (arthralgia or myalgia) are less common in infections with *S. minus* than in streptobacillary rat-bite fever. Most patients have a generalized red or purple macular rash that can be urticarial. The rash, usually prominent during the first week of illness and during febrile periods, may fade with resolution of symptoms. In untreated patients, high fever and systemic symptoms last for 3 to 7 days, remit, and recur 3 to 10 days later, followed by recurring cycles for 3 to 8 weeks. In severe cases, pneumonia, meningitis, myocarditis, or (especially in patients with preexisting valvular disease) endocarditis can develop.

S. minus has not been cultivated on artificial media but can be identified on darkfield microscopy and, occasionally, in Wright- or Giemsa-stained smears of peripheral blood. No serologic test is available. Organisms can be identified in guinea pig blood 2 to 3 weeks after intraperitoneal inoculation of infected blood.

S. minus is exquisitely susceptible to penicillin. Excellent response is expected with the use of procaine penicillin given intramuscularly (20,000–50,000 U/kg once daily), penicillin G given intravenously, or penicillin V given orally (1–2 g/day divided into 3 doses).[29–31] Streptomycin and tetracycline are effective alternative agents. Therapy is given for 10 to 14 days.

Anaerobic Bacteria

Classification, Normal Flora, and Clinical Concepts

Itzhak Brook, Sarah S. Long

Classification

Anaerobic bacteria predominate on normal skin and among the bacterial flora of mucous membranes.[1,2] Infections caused by anaerobic bacteria are common, arise from the sites where they are normal flora (endogenous), and can be serious or life-threatening. Anaerobic bacteria are fastidious, difficult to isolate, and often overlooked. Their recovery requires proper methods of collection, transportation, and cultivation.[3–7] Their ubiquity on mucocutaneous surfaces often interferes with obtaining meaningful cultures. Although no universally accepted or simple and accurate way has been established to classify microorganisms according to conditions required for their replication, Table 187.1 presents a useful framework for the clinician. Nevertheless, differences among strains exist within the same species.

TABLE 187.1

Classification of Microorganisms by Conditions of Replication

Class	Requirement for Replication	Examples
Strict anaerobe	Requires reduced oxygen tension; does not	*Bacteroides, Prevotella,*

	replicate on agar surface in air or 10% carbon dioxide	*Peptostreptococcus*, and *Fusobacterium* spp.
Microaerophilic organism	Replicates poorly on agar surface in the presence of oxygen but distinctly grows better under 10% carbon dioxide in air or anaerobically	Most streptococci of normal oropharyngeal flora
Facultative anaerobe	Replicates in the presence or absence of oxygen	Groups A, B, and C streptococci, *Streptococcus pneumoniae, Staphylococcus* spp., *Escherichia coli*
Strict aerobe	Replicates only in the presence of oxygen	Most *Pseudomonas* and *Mycobacterium* spp.

Anaerobic bacteria do not replicate in the presence of oxygen; however, they exhibit substantial differences in lethal effect of oxygen. In general, anaerobic organisms found exclusively as normal flora are strict anaerobes (i.e., die within minutes in <0.5% oxygen), whereas those of clinical significance are somewhat aerotolerant (i.e., tolerate 2% to 8% oxygen). Strict anaerobes do not grow in 10% carbon dioxide in air; microaerophilic bacteria can grow in 10% carbon dioxide in air or under aerobic or anaerobic conditions, and facultative organisms can grow in the presence or absence of air. The physiologic basis for oxygen sensitivity is not well understood. Common teaching is that negative oxidation-reduction potential (Eh) of the environment is the critical factor. However, studies with *Bacteroides fragilis* reveal that oxygen has a direct toxic effect; chemical manipulation of oxidation-reduction potential has no effect if oxygen is not introduced. Furthermore, aerotolerance and possibly virulence of anaerobic bacteria correlate with the ability to induce the protective enzyme superoxide dismutase on exposure to oxygen.[4]

The clinically important anaerobic genera are shown in Table 187.2. The taxonomy of anaerobic bacteria has changed because of improved characterization through the use of genetic studies.[3,5] Discriminating among strains enables better characterization of the source of infection and prediction of antimicrobial susceptibility. The genera and groups most frequently isolated from clinical infections, in descending frequency are: *Bacteroides/Prevotella* spp., *Peptostreptococcus* spp., *Clostridium* spp., *Fusobacterium* spp., gram-positive bacilli, and gram-negative cocci.[2,3]

TABLE 187.2

Genera of Clinically Significant Anaerobic Bacteria

GRAM-NEGATIVE BACILLI

Bacteroides (*B. fragilis* group and others)
Fusobacterium
Porphyromonas
Prevotella
Other Bacteroidaceae *(Bilophila, Centipeda, Leptotrichia, Mobiluncus, Seleonomonas, Sutterella)*
Campylobacter
GRAM-NEGATIVE COCCI
Veillonella
NON–SPORE-FORMING GRAM-POSITIVE BACILLI
Actinomyces
Arcanobacterium
Bifidobacterium
Eubacterium
Lactobacillus
Propionibacterium
ENDOSPORE-FORMING GRAM-POSITIVE BACILLI
Clostridium
GRAM-POSITIVE COCCI
Gemella
Parvimonas
Peptococcus
Peptostreptococcus
Ruminococcus
Staphylococcus (S. saccharolyticus)
Streptococcus[a] *(S. anginosus, S. constellatus, S. intermedius)*

[a] Microaerophilic streptococci.

The use of DNA technology (e.g., determination of DNA mole percent guanine plus cytosine content, ribosomal RNA homology, gel electrophoresis sequencing) and chemotaxonomic analyses (e.g., analysis of peptidoglycans, gas-liquid chromatography of whole cell fatty acids) has enlightened taxonomic relationships among anaerobic bacteria. Wide-ranging taxonomic changes have affected the family Bacteroidaceae and anaerobic gram-positive cocci. *Bacteroides melaninogenicus,* a single species until 1977, now encompasses 2 genera (*Prevotella* and *Porphyromonas*) and >15 species.[8] Minor changes have been made in the classification of gram-positive bacilli, and the genus *Eubacterium* remains heterogeneous and inadequately examined.

Indigenous Flora

Establishment and Composition of Normal Flora

The frequency of recovery of anaerobic bacteria as normal flora varies by body site and age. Table 187.3 shows sites of colonization of clinically important anaerobic bacteria. Mucocutaneous surfaces in humans have complex indigenous flora composed of anaerobic, microaerophilic, facultative, and aerobic bacteria. Flora is remarkably predictable within days after birth, depending on the type of delivery, feeding, and receipt of antibiotics.[9] Successive colonization of the gut simulates that in germ-free laboratory animals after exposure to peers.[10] Facultative organisms, such as oral streptococci, intestinal *Escherichia coli,* and skin staphylococci, precede anaerobic species, but by the end of the first few weeks of life, flora is complex and predictable. Infants fed human milk exclusively have a fermentative gut flora with predominance of *Bifidobacterium*, fewer *Bacteroides* and facultative gram-negative bacilli, and *Enterococcus* spp., whereas infants fed cow's milk have putrefactive flora similar to that of adults, with gram-negative anaerobic and facultative bacilli predominating.[11,12] Early colonization at <3 weeks with *B. fragilis* has been associated with the risk of asthma at a later age.[13] Remarkable perturbation of gut flora is noted at weaning from human milk,[14] and disruption of flora occurs with the use of antibiotics, especially in infancy.

TABLE 187.3

Selected Anaerobic Bacteria of Normal Flora

	Body Site (Ratio of Total Anaerobic to Aerobic Flora)[a]					
Bacteria	**Mouth (1,000 : 1)**	**Upper Respiratory Tract (4 : 1)**	**Upper Intestine (1 : 1)**	**Lower Intestine (1,000 : 1)**	**Lower Genitourinary Tract (5 : 1)**	**Skin (2 : 1)**
GRAM-POSITIVE BACILLI						
Actinomyces spp.	+	+	+/−	+	+/−	

Bifidobacterium spp.	+	+	+/−	++	+	
Eubacterium spp.	+	+/−		+	+	+/−

Prevotella spp. (other)	++	+		+	++	
Wolinella spp.	+	+		+		+/−
GRAM-NEGATIVE COCCI						
Veillonella spp.	++	+	+/−	+	++	

[a]Mouth includes gingiva, teeth, saliva, anterior mucosa; upper respiratory tract includes nasal passages, nasopharynx, oropharyx, and tonsils; upper intestine includes duodenum, jejunum, midileum; lower intestine includes lower ileum, colon, rectum; lower genitourinary tract includes vagina, urethra, genital skin in adults.

+/−, irregularly present; +, usually present; ++, usually present in large numbers.

Data from Shah HN, Gharbia SE. Progress in the identification of nonmotile Bacteroidaceae from dental plaque. Clin Infect Dis 1994;18(Suppl 4):S287–S292; Hentges DJ. The anaerobic microflora of the human body. Clin Infect Dis 1993;16(Suppl 4):S175–S180; and Finegold SM. Anaerobic bacteria: their role in infection and their management. Postgrad Med 1987;81:141–148.

Colonization of the mouth similarly is rapid and predictable. Viridans streptococci and *Streptococcus salivarius* are present and predominate, usually within 12 hours after birth, with successive representation by facultatively anaerobic *Neisseria* and *Staphylococcus* spp. and then anaerobic streptococci, *Veillonella,* and *Bifidobacterium* spp. on the second day.[15–17] Nasopharyngeal and oropharyngeal *Streptococcus pneumoniae,* nontypable *Haemophilus influenzae,* and *Moraxella catarrhalis* follow and remain as facultative flora throughout childhood. *Prevotella melaninogenica* becomes predominant at gingival crevices, seemingly under hormonal influences, at puberty.[15,16] Predominant oral flora organisms are *Prevotella, Porphyromonas, Fusobacterium,* and non-*fragilis Bacteroides* species.

Colonization of skin varies by site and age.[17,18] Coagulase-negative staphylococci (or *Staphylococcus aureus* in nurseries where it is prevalent) appear, followed by Enterobacteriaceae at diapered sites. *Propionibacterium acnes* becomes the dominant anaerobe, quantitatively accounting for almost one half of culturable flora at most anatomic sites; anaerobic cocci also are important. Anaerobic bacteria predominate in vaginal flora, even prepubertally, with gram-positive bacilli and cocci and *Prevotella* highly represented.[19]

Clostridium ramosum and *Clostridium perfringens* are dominant clostridial species in intestinal flora. *Clostridium difficile* is found in only 1% to 4% of healthy adults and children >6 months of age. Findings of asymptomatic colonization in up to 60% of infants in neonatal intensive care units in occasional studies probably reflect unusual nosocomial phenomena.[20]

The qualitative and quantitative complexity of flora and the difficulty of its study cannot be overestimated. Within the mouth, for example, the gingival crevice has an oxidation-reduction potential of −300 mV (similar to that in the colon); the ratio of anaerobes to aerobes is 1000 : 1, yet saliva and teeth have ratios closer to 1 : 1. The normal flora of the colon contains more than 500 obligate anaerobic species in a total concentration of 10^{11} to 10^{12} colony-forming units (CFU) per gram of feces, and most organisms are unculturable.[21] The predominant gram-negative anaerobes are *Bacteroides* and *Fusobacterium* spp. Although <0.1% of normal flora consists of facultative or aerobic organisms (e.g., 10^8 CFU/g of feces), ease of recovery from endogenous infections has led to overestimation of their importance of these organisms in the microbial ecology of the gut. Similarly, the erroneous tendency is to focus on the clinically most significant anaerobic bacteria as critical in ecology. *B. fragilis,* for example, is quantitatively among the least important species of the *Bacteroides* group in normal flora. Animal models and continuous-flow in vitro culture models have been established to study microbial ecology, mechanisms of microbial interaction, and the importance of microbes in health; studies are painstaking, and conclusions are difficult to establish.[22]

Anaerobes reach a concentration of 10^6 organism/mL in vaginal secretions, with predominance of *Prevotella, Bacteroides, Fusobacterium,* and *Clostridium* spp. Anaerobes isolated most commonly from clinical specimens are *Prevotella bivia* and *Prevotella disiens.*[17]

Role of Indigenous Flora

Multiple observations lead to the conclusion that indigenous, especially anaerobic, flora organisms provide resistance to colonization and invasion by nonindigenous microorganisms. A few such observations follow:

1. Infants in an intensive care nursery are at higher risk of pharyngeal colonization with potentially pathogenic organisms if they are not colonized initially with viridans streptococci.[16]

2. Children who are colonized with group A *Streptococcus* (GAS), have recurrent GAS tonsillitis, or have recurrent otitis media or sinusitis are less likely to have inhibitory facultative (α-hemolytic streptococci) and anaerobic (*Prevotella* and *Peptostreptococcus* spp.) oropharyngeal flora.[23]

3. *Propionibacterium* spp. hydrolyze triglycerides, thus producing free fatty acids that are inhibitory to GAS and *S. aureus.*[17]

4. Primary metabolic byproducts of anaerobes, volatile fatty acids, inhibit the multiplication of nonindigenous organisms in the intestine.[17]

5. *Lactobacillus* spp. produce hydrogen peroxide, which is bactericidal for *P. bivia*, and *Gardnerella vaginalis* presence in vaginal flora is inversely related to bacterial vaginosis.[24]

6. Susceptibility of germ-free mice to colonization and outgrowth of *Clostridium botulinum* can be manipulated dramatically by selective colonization, especially with anaerobic flora.[25]

7. Infant botulism occurs exclusively in the first year of life, especially at the time of perturbation of anaerobic gut flora at weaning.[14]

8. *C. difficile* pseudomembranous colitis is highly associated with the use of antibiotics. Protection from colonization or cure of disease can be afforded to animals and humans by intestinal administration of probiotics or fecal transplant.[26–28]

9. Experimental infectivity of *Salmonella* or *Shigella* spp. is enhanced by pretreatment of animals with antibiotics; infectivity is reduced when germ-free animals are fed mixed cultures of pathogens with anaerobic bacteria.[29]

10. Susceptibility of children <2 years of age to all enteric pathogens correlates with the relative ease of disruption of indigenous flora.

11. In a double-blind, placebo-controlled trial, infants 5 to 24 months old who were admitted to a longterm care facility and whose formula was supplemented with *Bifidobacterium bifidum* and *Streptococcus thermophilus* had significantly less diarrhea and shedding of rotavirus.[30]

12. Prophylactic administration of a probiotic mixture of *Lactobacillus acidophilus* and *Bifidobacterium infantis* given to very low birth weight infants reduced the incidence of all cases of necrotizing enterocolitis as well as severe stage III necrotizing enterocolitis.[31]

13. The ability to interfere with potential pathogens has been observed for *B. fragilis, Prevotella oralis, Peptostreptococcus anaerobius, Veillonella* spp., and *Bifidobacterium* spp.[32]

Mechanisms by which normal flora provide resistance to colonization have been reviewed.[23,33,34] They include (1) production of bacteriocins and other metabolic products (e.g., volatile fatty acids) that inhibit multiplication of nonindigenous flora at local conditions of pH and oxidation-reduction potential, (2) competition for limited nutrients, and (3) competition for available attachment sites. Host factors undoubtedly provide exquisitely specific microbial niches by means of the unique properties of epithelial surfaces, enzymes, secretory immunoglobulins, pH, nutrients, exfoliation of skin and mucous membranes, motility of the gastrointestinal tract, and mucociliary movement in the respiratory tract. Coliform organisms are present in the oropharyngeal or nasopharyngeal flora of only approximately 3% of healthy adults[35] and children.[36–38] Severe noninfectious illness, viral infection, malignant disease, diabetes, chemotherapy, antibiotic therapy, and antacid therapy affect changes in colonizing bacteria.[37] Changes in attachment properties of epithelial cells in vitro correlate with changes in flora.[39] A relative or absolute increase in nasopharyngeal *S. pneumoniae, H. influenzae,* or *M. catarrhalis* occurs in association with viral illness and acute otitis media, and it predicts the presence of concordant middle ear pathogens in the acute otitis media.[36,38]

Organisms of the normal anaerobic intestinal flora also have broadly ranging metabolic effects, mainly through provision of catabolic enzymes for organic compounds that cannot be digested by enzymes of eukaryotic origin. The enzymes are necessary to: (1) process diverse dietary and host polysaccharides, thus aiding human digestion[40]; (2) catabolize cholesterol, bile acids, and steroid hormones; (3) hydrolyze certain flavonoid glycosides of plant origin to anticarcinogens; and (4) detoxify certain carcinogens and drugs.[41] Erythromycin or tetracycline treatment raises the serum digoxin level 50%, almost certainly by reducing gut *Eubacterium lentum,* which inactivates digoxin through hydrogenation of the double bond of its lactone ring.[42]

Normal flora provides “education” of the host's immune system from birth onward, and possibly earlier. Germ-free animals (and probably heavily antibiotic-exposed infants) have immune defects, such as diminished production of complement and immunoglobulins as well as reticuloendothelial and lymphoid tissues.[37] *B. fragilis* zwitterionic polysaccharide A regulates an immunologic equilibrium in the intestine by balancing colonic helper T lymphocytes, subtypes 1 and 2, and promotes anti-inflammatory interleukin-10 production.

Role of the Human Microbiome in Health and Disease

The pool of microbes inhabiting the body, the microbiota, and their collective genomes, the metagenome, comprise the microbiome. The metabolome acknowledges presence and function of microbial metabolites. The healthy human microbiome is the consequence of highly regulated host-microbial interactions. These interactions have been unraveled.[37,43] The colon is the most densely populated organ in the human body, although other surfaces (e.g., the skin, vaginal or respiratory mucosa) also harbor specific microbiota. The very existence of “commensal” aerobic and anaerobic bacteria in the gut, oropharynx, and nasal cavity infers their useful purpose.

This now has been confirmed for processes such as digestion of food and development of immune tolerance to avoid certain autoimmune and allergic diseases.

Alterations in composition and function of the microbiota have been associated with several gastrointestinal diseases (inflammatory bowel disease, colorectal cancer or irritable bowel syndrome), as well as extraintestinal diseases, such as those affecting the liver or the respiratory tract (e.g., allergy, bronchial asthma, and cystic fibrosis), among others.[44]

Effect of Antimicrobial Agents

The effect of antibiotics on normal flora is extremely complex and varies with dose and route of administration, spectrum of antimicrobial activity (breadth, potency, and specificity for anaerobes), and chemical and pharmacokinetic properties. The clinical impact depends on the duration of antibiotic use, the presence and severity of underlying conditions, exposure to nonindigenous pathogens (*Pseudomonas, C. difficile*), and host susceptibility to indigenous and nonindigenous microbes (underlying valvular heart disease, malignant disease, surgical procedures, inserted devices, and age). In general, agents that have a major impact on anaerobic flora cause the greatest disruption of homeostasis.

The main determinant of effect on oropharyngeal flora is secretion of the agent in saliva or from mucous membranes, thus correlating with lipophilicity. Clindamycin, erythromycin, and rifampin are present in high concentrations; penicillins and ampicillin, despite relatively low concentrations, have potent activity against oral facultative and anaerobic bacteria. The use of β-lactam antibiotics (even penicillin) may not supplant a species from its microbial niche but can select for organisms in the oropharynx and nasopharynx with reduced antimicrobial susceptibility (*S. pneumoniae,*[45] viridans streptococci)[46] or β-lactamase production (*Moraxella, Prevotella* spp.).[47] The nasopharyngeal flora are depleted of organisms with protective potential more with amoxicillin-clavulanate therapy than with a narrower-spectrum agent.[48]

The most profound effects on gut flora occur with administration of agents that have exquisite activity against anaerobic bacteria, which are present in high concentration at the ileal-colonic mucosa. The pharmacodynamics of specific agents is important. Exquisite activity against anaerobes (clindamycin, amoxicillin-clavulanate), high biliary excretion (ceftriaxone, cefoperazone), or the use of oral nonabsorbable agents (neomycin, gentamicin) ensures an effect on flora, but high absorption of oral agents does not necessarily predict low colonic concentrations because antibiotic is delivered to the mucosal site by blood (amoxicillin).[49] Outgrowth of *Enterococcus* and *Candida* spp. occurs rapidly when potent agents have selective nonactivity (aztreonam, ceftriaxone, cefoxitin)[50–53] or poor activity (imipenem) for enterococci.[54] The β-lactamases of certain facultative organisms (the SPACEY group [*Serratia, Pseudomonas, Acinetobacter, Citrobacter, Enterobacter,* and *Yersinia* spp.]) can be induced by cefoxitin and several third-generation cephalosporins[4,55]; β-lactamase production by anaerobes can increase[56]; or resistant nosocomial pathogens can be acquired. The use of broad-spectrum, exquisitely active cephalosporins, carbapenems, and fluoroquinolones with profound effects on normal flora undeniably have changed the incidence, microbiology, and susceptibility of superinfecting microbes in children.[55,57,58] Attempts to reconstitute flora, as with lactobacilli, have an overall positive but uncertain impact.[23,59]

Pathogenesis

Anaerobic infections are predictable because these organisms are not intrinsically highly pathogenic. Most anaerobic infections are caused by the host endogenous flora and occur at sites contiguous or related to sites of their normal residence, under permissive or instigating circumstances. Such circumstances include the following: (1) access to deep tissue through surgical intervention, trauma, tuberculous lesions, endoscopic procedures, right-to-left cardiac shunt, perforation of viscus, or massive aspiration of oropharyngeal flora; (2) impairment of normal clearance of a hollow viscus (obstruction by a foreign body, fecalith, stricture, tumor, lymph node), decreased patency of a respiratory passage (chronic otitis media and sinusitis), or dysfunctional mucociliary movement, cough, or alveolar macrophage function; and (3) lowering of oxygen reduction potential through tissue necrosis (surgical intervention, trauma), impairment of blood supply, or the presence of infection with aerobic bacteria or foreign material (aspirated foreign body, sutures, catheter, intrauterine device).

Traditionally defined host susceptibility factors (e.g., disorders of complement, hypofunction of spleen, human immunodeficiency virus infection, and cellular immune deficiencies) increase risk of infection with facultative and aerobic pathogens but generally not with anaerobic infections. Severe debilitation, malnutrition, diabetes, corticosteroid use, collagen vascular disease, cytotoxic drugs, neutropenia or neutrophil dysfunction, malignant diseases, and lymphopenia are associated with anaerobic necrotizing soft tissue infections and other invasive disease. Certain specific associations have been observed between some underlying diseases and infections involving anaerobic bacteria. They include acatalasemia with oral gangrene, trisomy 21 or human immunodeficiency virus infection with severe periodontal disease, colon cancer and neutropenia with clostridial infection and colitis, and diabetes mellitus with cholecystitis and osteomyelitis.[2,3] In an animal model, T-lymphocyte–mediated responses governed protection from *B. fragilis.*[60] *B. fragilis* bacteremia was reported in several children who underwent elective appendectomy at the time of renal transplantation and corticosteroid therapy; infection was correlated with severity of lymphopenia.[61,62]

A few anaerobic infections are of exogenous origin. These include gas gangrene after trauma, *C. difficile*–associated disease, *C. perfringens* food poisoning or diarrhea, infant botulism, and *Clostridium botulinum* and *Clostridium tetani* wound infections.

Anaerobes responsible for infection do not always correlate with their quantitative presence in normal flora. *B. fragilis, Fusobacterium necrophorum, Fusobacterium nucleatum, P. melaninogenica,* and *Actinomyces israelii* are highly overrepresented, implying specific virulence. *Bilophila wadsworthia* is associated specifically with acute appendicitis,[63] *Clostridium septicum* with typhlitis and septicemia in hematologic malignant disease,[64] *Eubacterium* and *Actinomyces* spp. with intrauterine devices,[65] and *Peptostreptococcus* and *Propionibacterium* spp. with prosthetic devices,[66] thus implying specific microbial niches. Additionally, spore-forming anaerobes, *C. botulinum, C. difficile,* and *C. tetani,* produce potent exotoxins that are responsible primarily for disease manifestations.

Virulence factors of anaerobic bacteria have been reviewed,[67] and they include the following:

- Promotion of adhesion by capsular polysaccharide and fimbriae (*B. fragilis*) and lectin (*F. nucleatum*)
- Invasion by phospholipase C (*C. perfringens*), lipopolysaccharides (*Porphyromonas gingivalis, F. nucleatum, F. necrophorum, Prevotella* spp.), and protease (*B. fragilis, F. nucleatum, F. necrophorum, Prevotella* spp.)
- Tissue infection and damage by multiple exoenzymes, such as fibrinolysin, neuraminidase, heparinase, *N*-acetylglucosaminidase (*B. fragilis, Porphyromonas,* and others), and collagenase (*C. perfringens*)
- Capsular resistance to phagocytosis, macrophage migration, and lysis by immunoglobulin A protease (*B. fragilis, Porphyromonas, Prevotella* spp.).[68] The capsule of *B. fragilis* activates host $CD4^+$ T lymphocytes, the release of interleukin-17 and chemokines,[69] and tumor necrotic factor-α and interleukin-1β from peritoneal macrophages. These cytokines lead to an increase in neutrophil adherence to mesothelial cells and abscess formation.[70]
- Production of other toxins and enzymes (elastase, hydrolytic enzymes, fibrinolysin, chondroitin sulfatase, lipase, lecithinase, gelatinase, immunoglobulin protease, botulinum toxin, tetanolysin, neuraminidase, leukocidin), various other leukotoxins (volatile fatty acids, hemolysins, hemagglutinins, lysophospholipase, proteases), endotoxins, deoxyribonuclease, ribonuclease, phosphatase, heparinase, other proteases, and other sulfatases
- Production of metabolites that are harmful to other bacteria, such as volatile fatty acids, sulfur compounds, and amines (most anaerobes)
- Production of lipopolysaccharide (*F. necrophorum*) that stimulates host-mediated damage
- Production of superoxide dismutase and catalase that permits aerotolerance

Certain clinical findings that typify anaerobic infection, such as abscess production (*B. fragilis*), burrowing through tissue planes (*A. israelii*), phlebitis, thrombosis, persistent bacteremia (*Bacteroides,* *Fusobacterium* spp.), and putrid purulence, are caused by specific components of organisms or their metabolic byproducts.[71] Although *Fusobacterium* spp. produce biologically active endotoxin, the endotoxins of *B. fragilis* and *P. melaninogenica* are chemically different and biologically inactive compared with those of coliform organisms.

An experimental animal model of intra-abdominal infection and septicemia has been studied extensively, and corollaries in the pathophysiology of human infection have been observed.[72] In summary, intraperitoneal inoculation of cecal contents, with an adjuvant such as barium sulfate or hog mucin, led to death in almost one half of animals in the first 4 days after challenge, always from *E. coli* septicemia (although the inoculum was polymicrobic). All surviving animals later demonstrated abscesses, with predominant isolation of *B. fragilis.* “Antibiotic probes” confirmed relative bacterial roles; after microbial challenge, administration of clindamycin (which activity excludes *E. coli*) did not reduce the mortality rate compared with untreated animals, but only 5% of the surviving animals had abscesses, whereas administration of gentamicin (which activity excludes *B. fragilis*) reduced the mortality rate to 4%, and 98% of surviving animals had abscesses. Administration of both antibiotics showed salutary advantages of each drug. Although these experiments suggest separate roles of microorganisms, synergistic roles of anaerobe with anaerobe, and with facultative anaerobe and aerobe, are more likely. Synergistic pathogenesis is supported by the observation of complexity of anaerobic infections (average of 3–6 microbial species), as well as by unsuccessful attempts to induce singular anaerobic infections in experimental models. The “synergy” provided could be the creation of a favorable milieu or pH, the provision of an obligatory vitamin, or an enzyme to enhance tissue spread.

Anaerobic bacteria can produce certain growth factors that confer their own selective advantage or can facilitate synergistic capabilities with other bacteria. These factors include hemin, succinate, menadione, peptides, amino acids, and steroids. Critical study remains elusive; simple therapeutic elimination of the facultative partner or partners does not reliably eradicate existing infection.[67]

Clinical Clues and Approach

Although anaerobic infections overall are not common in children and account for <2% of bloodstream infections (BSIs) in childhood, certain clinical settings or characteristics of infection are so typical as to make diagnosis of anaerobic infection almost certain (Table 187.4). Equally important, confirmation of an anaerobic infection mandates explanation of or investigation for a predisposing event or circumstance. For example, bronchoscopy is indicated for unexplained anaerobic lung abscess or empyema in children (if congenital pulmonary sequestration or cyst is not likely) or to remove a foreign body (despite a forgotten or negative history) or obstructing granulation tissue. Repeated pneumonia, bronchiectasis, or hemorrhage otherwise will result.

TABLE 187.4

Clinical Clues to Infection With Anaerobic Bacteria

Predisposition and Characteristics	Examples and Comments
PREDISPOSITION	
Infection contiguous to site of mucosal colonization	Sinuses, periodontal, oropharyngeal-orofacial (noma) pulmonary, periappendiceal, intra-abdominal, perirectal sites
Obstruction or perforation of hollow viscus	Nasal or pulmonary foreign body or anatomic abnormality, bronchiectasis, perforated appendix, chronic cervicitis or salpingitis, surgical breach of mucosa
Disruption of normal clearance mechanism	Impaired cough, gag, laryngopharyngeal function, mucociliary movement, alveolar macrophage function; unconsciousness
Excessive bacterial inoculation	Periodontal disease, massive aspiration, bite wound, right-to-left cardiac-pulmonary shunt, surgical peritoneal soilage
CHARACTERISTICS	
Marked tendency to tissue necrosis and abscess formation	Necrotizing pneumonia or lung abscess, tubo-ovarian or intra-abdominal abscess
Necrotizing cellulitis or myositis, sometimes with gas or gangrene and abscess formation	Meleney synergistic gangrene, noma,[98] and omphalitis (severe underlying malnutrition, crush injury, or ischemic tissue expected); *Clostridium*, *Peptostreptococcus*, *Bacteroides* spp. produce gas, but so do coliforms and *Pseudomonas*
Putrid exudate, putrid breath	Pathognomonic but present in less than half of anaerobic abscesses, related to volatile fatty acid byproducts; severe halitosis can be the initial or predominant complaint in nasal foreign body or lung abscess
Marked tendency to septic thrombophlebitis	Pelvic thrombophlebitis with appendiceal or genital tract infection; jugular vein thrombosis with oropharyngeal infection; clues are persistently positive blood culture or pulmonary septic emboli
Polymicrobial Gram stain of exudate	Pathognomonic; irregular uptake of Gram stain and pleomorphic, gracile, beaded, or branched morphologic features also a clue
Failure to isolate	"Sterile pus," despite positive Gram stain, especially if processing

pathogens in aerobic cultures or isolation of facultative normal flora	inadequate; isolation of microaerophilic streptococci or *Aggregatibacter* (formerly *Actinobacillus*) *actinomycetemcomitans*
Failure to respond to antibiotics without activity against anaerobes	Failure of monotherapy aminoglycoside for *Escherichia coli* intra-abdominal abscess, penicillin for lung abscess, cephalosporin for brain abscess

Intra-abdominal polymicrobial abscess in children is almost always the result of subacute ruptured appendix.[73] Table 187.5 lists infections that commonly (chronic sinusitis, aspiration pneumonia, brain abscess) or virtually always (bite or periappendicular abscess) involve anaerobic bacteria. Characteristic syndromes occur, such as that of Lemierre[74] (see Chapter 193). The triad of parenchymal lung infection, osteomyelitis of a contiguous rib, and soft tissue abscess is typical of actinomycosis[75] (see Chapter 195). Putrid odor of breath can be the clue to the presence of a nasal foreign body or anaerobic lung abscess.[76]

TABLE 187.5

Infections Commonly Involving Anaerobic Bacteria in Children and Adolescents

Oropharyngeal Flora	Intestinal or Genital Flora
Chronic sinusitis Chronic otitis media Subacute or chronic, tonsillar, parapharyngeal, peritonsillar, or parotid abscess Gingivitis, odontofacial cellulitis or abscess, noma Ludwig angina (sublingual and submandibular infection) Lemierre infection (posterior and lateral pharyngeal infection) Bite or clenched fist, fight injury abscess Paronychia Septicemia or metastatic infection related to lymphoreticular malignancy Infection of congenital cyst (pulmonary, cervical, thryroglossal) Aspiration pneumonia Necrotizing pneumonia Pneumonia with empyema Lung abscess Pneumonia–rib osteomyelitis–soft tissue abscess triad Superinfected bronchiectasis Subdural or epidural empyema Brain abscess (after sinopulmonary	Wound abscess after intestinal, genitourinary surgical procedures Perirectal, pilonidal abscess Infection related to enterocutaneous or genitourinary fistula (acquired or congenital) Peritonitis and abdominal abscess secondary to intestinal perforation (spontaneous or surgical) Periappendiceal, subphrenic, guttural abscess Hepatic, pancreatic, splenic, nephric abscess Obstructive cholangitis Septicemia or metastatic abscess related to intestinal tumor or abdominal infection Meningitis, brain abscess associated with anterior meningomyelocele; after instrumentation, dilation, surgical procedures, or trauma to colon or rectum; metastatic from *Bacteroides fragilis* bacteremia in neonate Bartholin abscess Infection related to vaginal or endometrial foreign body, surgical procedures, or instrumentation Pelvic inflammatory disease Tubo-ovarian abscess Suppurative pelvic thrombophlebitis Puerperal septicemia

infection or operation, tracheal or esophageal instrumentation for dilation, congenital heart disease)	

Microbiologic Methods

Specimen Collection

The diagnosis of anaerobic infection requires collection of appropriate specimens followed by their expeditious transportation and careful laboratory processing. The use of inadequate techniques or media can lead to an erroneous assumption that only aerobic organisms are present in a mixed infection (Table 187.6).[3] Specimens must be obtained with techniques that bypass the normal flora. Direct needle aspiration or surgical exposure is the best method of obtaining a specimen for culture (see Table 187.6).

TABLE 187.6

Methods for Collection of Specimen for Anaerobic Bacteria

Infection Site	Methods
Abscess or body cavity	Incised abscesses—syringe or swab (less desirable); specimen obtained during surgical procedure after skin is cleansed
Tissue or bone	Surgical specimen using tissue biopsy or curette
Sinuses or mucous surface abscesses	Aspiration after decontamination or surgical specimen
Ear	Aspiration after decontamination of ear canal and membrane; in perforation, cleanse ear canal and aspirate through perforation
Pulmonary	Transtracheal aspirate, lung puncture, bronchoscopic aspirate[a]
Pleural	Thoracentesis
Urinary tract	Suprapubic bladder aspirate
Female genital tract	Intrauterine brush specimen[a]

[a] Using double-lumen catheter and quantitative culture.

Transport

Liquid or tissue specimens always are preferred to swabs. Specimens should be placed into an anaerobic transporter immediately. These devices generally contain an oxygen-free environment, provided by a mixture of carbon dioxide, hydrogen, and nitrogen, in addition to an aerobic condition indicator. A liquid specimen is inoculated into an anaerobic transport vial. A syringe also can be used after all air bubbles are expelled. Because air gradually diffuses through the plastic syringe wall, however, specimens should be processed in <30 minutes. Swabs are placed in sterilized tubes containing carbon dioxide or prereduced, anaerobically sterile Cary and Blair semisolid media. A tissue specimen can be transported in an anaerobic jar or in a sealed plastic bag that has been rendered anaerobic.

Several transport systems have been developed and are useful in certain settings, such as for smaller specimens, with delayed processing, or unavoidable use of a swab specimen (Table 187.7). Compared with the Vacutainer (Becton, Dickinson, Franklin Lakes, NJ)anaerobic specimen collector, the Port-A-Cul (Becton, Dickinson) was found to be superior for isolation of anaerobic bacteria from abscesses in one study, especially when transit time was >24 hours.[77]

TABLE 187.7

Specimen Transport System for Anaerobic Bacteria

Type of System	Examples
HOLDING SYSTEM	
Enclosed tube or vial, anaerobic atmosphere, isotonic agar, moist environment	Port-A-Cul system (Becton, Dickinson, Franklin Lakes, NJ) Anaerobic transport medium (Anaerobe Systems, Morgan Hill, Calif) Agar gel transport swab[a] (Copan Diagnostics, Murietta, Calif)
PREREDUCED MEDIA SYSTEM	
Tube with anaerobic atmosphere and prereduced, anaerobically sterilized (PRAS) medium	Anaerobic transport system (Starplex Scientific, Cleveland, Tenn) Anaerobic Transport Medium (Anaerobe Systems, Morgan Hill, Calif)

[a] Care should be taken to flick off excess gel when preparing Gram stain because the gel itself can contain nonviable but Gram-stainable organisms.

Direct Examination

The general appearance (necrosis, purulence) and putrid odor of the specimen can suggest the presence of anaerobes. Inspection of clinical specimens can reveal sulfur granules, which are pathognomonic for *Actinomyces* infection. Gram stain can provide important clues, as follows[4]: (1) the presence of multiple species typifies anaerobic infection; (2) certain morphologic features are discernible (pale-staining pleomorphic *Bacteroides,* gracile fusiform *Fusobacterium,* tiny gram-negative coccal *Veillonella,* branching *Actinomyces,* boxcar *Clostridium*); and (3) findings aid interpretation of the relative importance of subsequent isolates or a sterile culture result. Immunofluorescence staining of specimens can be helpful in detection of special organisms, such as *Propionibacterium propionicum* and *Actinomyces* spp. However, this method is not yet sufficiently refined to be used for the detection of gram-negative anaerobic bacilli. Direct analysis for characteristic short-chain fatty acids by gas-liquid chromatography has been applied to blood cultures and exudate specimens, as have detection methods for *C. difficile* to stool specimens (see Chapter 190). Each examination method has limitations of practicality, sensitivity, or cost. Nucleic acid probes can detect and identify anaerobic organisms (especially for *Bacteroides* spp. and potential periodontal pathogens), and polymerase chain reaction can detect oral anaerobes, *C. difficile,* and toxins.[3] In addition, 16S (small subunit) ribosomal RNA gene sequencing can be used for strains that cannot be identified phenotypically.

Primary Isolation

Table 187.8 lists media used for primary isolation of anaerobic bacteria. Because most infections are polymicrobial, optimal recovery requires the use of nonselective and selective aerobic and anaerobic media. A minimum for isolation of anaerobic bacteria is inoculation onto supplemented blood agar and a medium selective for growth of *B. fragilis* and *Prevotella* groups (see Chapter 286).

TABLE 187.8

Media Used for Recovery of Anaerobic Bacteria

Media	Purpose
NONSELECTIVE MEDIA	
Anaerobic blood agar: *Brucella*, brain-heart infusion with yeast extract, Columbia, CDC (Centers for Disease Control and Prevention), Schaedler	Supports growth of anaerobic and facultatively anaerobic bacteria; requires vitamin K supplementation; CDC agar best for cocci, *Brucella;* Schaedler best for gram-negative bacilli
SELECTIVE MEDIA	
Bacteroides bile esculin (BBE) agar	Selects growth of *Bacteroides fragilis* group, and most hydrolyze esculin to brown-black colonies; contains bile and gentamicin, which inhibit most other

	organisms
Kanamycin-vancomycin laked blood (KVLB) agar	Selects growth of *Bacteroides* and *Prevotella* spp.; enhances pigment production of *Prevotella melaninogenica*
Phenylethyl alcohol (PEA) sheep blood agar	Supports growth of anaerobic bacteria; inhibits coliforms
Colistin-nalidixic acid blood agar	Selects growth of gram-positive bacteria; inhibits gram-negative bacteria
Cycloserine-cefoxitin-fructosec agar (CCFA)	Selects growth of *Clostridium difficile*
ENRICHMENT BROTHS	
Enriched thioglycolate (BBL-135C), chopped meat broth	Used in addition to agar, as holding, enrichment media for slow-growing organisms and for heat shock treatment for selection of spore-forming bacteria; requires vitamin K and hemin

Susceptibility Testing

Antimicrobial susceptibility patterns of anaerobes have become less predictable. Resistance to several agents, especially by gram-negative bacilli, has increased.[78,79] Screening of anaerobic gram-negative bacilli isolates for β-lactamase activity can be helpful. However, occasional strains can be resistant through other mechanisms. Susceptibility testing of anaerobes should be performed primarily to determine the activity of new agents and to monitor local, national, or international susceptibility patterns periodically. Susceptibility testing should be performed on organisms that are recovered from sterile body sites, on organisms isolated in pure culture, or on organisms that are clinically important and have unpredictable or unique susceptibility patterns. Highly virulent pathogens for which susceptibility cannot be predicted include *Bacteroides, Prevotella, Fusobacterium,* and *Clostridium* spp., *Bilophila wadsworthia,* and *Sutterella wadsworthensis*. Testing of an individual patient's isolates also can be required for serious or chronic infection, such as endocarditis, bacteremia, osteomyelitis, brain abscess, or device-related infection.[80]

Problems in antimicrobial susceptibility testing of anaerobic bacteria include lack of standardization of techniques, idiosyncrasies and fastidiousness of bacterial growth, appropriate choice of antimicrobial susceptibility breakpoints, clustering of isolates at breakpoints, lengthy testing period, and limited clinical correlation of in vitro observations. Treatment usually is based on statistical knowledge of suspected or proven pathogens and antimicrobial susceptibility patterns as tested in batches in reference laboratories. Problems with the antimicrobial susceptibility testing in reference laboratories include sources of test strains (clinical isolates versus laboratory strains versus normal flora), currency, number and relevance of representative species, and accuracy of identification.

The standardization of testing methods by the Clinical and Laboratory Standards Institute (CLSI) allows comparison of resistance trends across various laboratories.[81] This organization describes 2 reference methods (agar dilution and broth microdilution) and emphasizes that other techniques, such as gradient techniques (generally referring to E-test) or commercial broth microdilution plates, can be used as long as equivalence to the reference methods is established.[82] Nitrocefin (chromogenic cephalosporin) testing is useful for the detection of β-lactamase production and attendant resistance of *Bacteroides* spp. and *P. melaninogenica* to β-lactam agents; however, resistance of some *Bacteroides* spp. (especially *B. gracilis* and *B. distasonis*) can occur by other mechanisms, and hydrolysis of imipenem and cefoxitin may not be predicted accurately.[83,84]

Mechanisms of Resistance

Mechanisms of antibiotic resistance of anaerobic bacteria are at least as broad as those for facultative and aerobic organisms; they include β-lactamase inactivation, hydrolysis, blocking of drug target site, alteration in affinity of penicillin-binding proteins, ribosomal protection or alteration, active efflux, RNA methyltransferase, and production of adenyltransferase and acetyltransferase.[84] Determinants of resistance are transferable by multiple mechanisms, such as a conjugation-like process, transposons, plasmid self-transfer, and mobilization. At the genetic level, some resistance determinants are highly specific for one or several anaerobes or can exhibit homology with genes from facultative bacteria.[83,85]

Treatment

Principles of Management

Managing principles for anaerobic infections are (1) neutralization of toxins; (2) prevention of local proliferation of bacteria by changing the environment and (3) deterrence of bacterial spread.[86] Toxin neutralization by specific antitoxins is essential in infections caused by certain clostridia (tetanus and botulism). Control of the environment is achieved by débriding necrotic tissue, draining pus, improving circulation, alleviating obstruction, and increasing tissue oxygenation. Debridement and removal of foreign bodies are essential for successful therapy. Drainage of abscesses also is important, although certain small or multifocal tubo-ovarian, brain, and intra-abdominal abscesses can respond to antimicrobial therapy alone or in combination with percutaneous aspiration or catheter drainage.[87–90] Lung abscesses commonly drain spontaneously, or bronchoscopy is performed for diagnostic and therapeutic reasons; empyema must be drained. Lobectomy or decortication should not be performed because resolution, even of necrotizing infection, is surprisingly complete.

The use of clostridial antitoxin for gas gangrene is still controversial because (1) the necessity is less clear with aggressive surgical debridement, and (2) immediate anaphylaxis and delayed serum sickness are attendant risks.[91] The use of specific antitoxins for management of botulism, tetanus, and diphtheria is addressed in the individual chapters on these diseases.

Certain types of adjunctive therapies (e.g., such as hyperbaric oxygen therapy for infection with spore-forming gram-positive anaerobic bacilli) are controversial but can be useful. Uncontrolled reports demonstrate efficacy in individual cases.[92] The use of hyperbaric oxygen therapy is contraindicated when it could delay other essential procedures. The topical application of oxygen-releasing compounds can be useful.

Surgical therapy is the most important, and sometimes the only, form of treatment required. This includes drainage, debridement, resection, restoration of airspaces, or maintenance of blood supply. Some of these procedures can be performed percutaneously when assisted by computed tomography, magnetic resonance imaging, or ultrasonography.

Few controlled, comparative efficacy studies of treatments of anaerobic infections have been conducted, and no clinical data are available for many microbes and antimicrobial agents. Additionally, most studies involve adults or are case reports involving children. Investigations in the 1970s showed lower mortality rates in patients with anaerobic BSIs who were treated with appropriate antimicrobial agents. Later case reports and series of BSIs related to devices or malignant disease collectively suggested clinical failure of therapy using agents without activity in vitro.[93,94] The notion that treatment of infection with facultative or aerobic copathogens is sufficient for cure can be correct early in the course of certain infections, such as aspiration pneumonia and paranasal sinusitis, especially when drainage can be promoted. Established, necrotizing infections, abscesses, or BSIs, however, require specific use of effective agents. Randomized clinical studies have shown superiority of clindamycin over penicillin,[95,96] and of clindamycin over metronidazole,[97] for treatment of anaerobic lung abscess or necrotizing anaerobic pneumonia.

Antimicrobial Agents

Susceptibility of anaerobic bacteria to antimicrobial agents is shown in Table 187.9, and drugs of choice are listed in Table 187.10. Certain agents have activity against virtually all anaerobes: carbapenems (imipenem, meropenem, doripenem), chloramphenicol, and β-lactam agents combined with a β-lactamase inhibitor.[98,99] Metronidazole is the most bactericidal agent against *Bacteroides* spp. and other gram-negative anaerobes, but it has variable or minimal activity against important gram-positive cocci and bacilli, including *Actinomyces* and *Lactobacillus* spp., and some *Propionibacterium* spp. *B. fragilis* resistance to clindamycin is increasing worldwide, and clindamycin no longer is recommended as empiric therapy for intra-abdominal infections.[100–104] A study of pediatric intra-abdominal isolates revealed clindamycin resistance in only 6% of *B. fragilis* isolates, compared with 80% for *B. thetaiotaomicron* and 45% for other *B. fragilis* group isolates.[105] Resistance also has increased for many non-*Bacteroides* anaerobes including up to 10% for *Prevotella, Fusobacterium, Porphyromonas,* and *Peptostreptococcus* spp. and *Propionibacterium acnes*, with higher rates for some *Clostridium* spp. (especially *C. difficile*).[104]

TABLE 187.9

Susceptibility of Anaerobic Bacteria to Antimicrobial Agents[a]

Bacteria	Penicillin	A Penicillin and a β-Lactamase Inhibitor	Ureidopenicillin or Carboxypenicillin	Cefoxitin	Chloram-phenicol	Clindamy
Peptostreptococcus spp.	4	4	3	3	3	3
Fusobacterium spp.	3–4	3–4	3	3	3	2–3
Bacteroides fragilis group	1	4	2–3	3	3	2-3
Prevotella and *Porphyromonas* spp.	1–3	4	2–3	3	3	3–4
Clostridium perfringens	4	4	3	3	3	3
Clostridium spp.	3	3	3	2–3	3	2
Actinomyces spp.	4	4	3	3	3	3

[a] Degrees of activity: 1, minimal; 2, moderate; 3, good; 4, excellent.

TABLE 187.10

Drugs of Choice for Infections Caused by Anaerobic Bacteria

Bacteria	First Choice	Alternative
Peptostreptococcus spp.	Penicillin	Clindamycin, chloramphenicol, cephalosporins
Clostridium spp.	Penicillin	Metronidazole, chloramphenicol, cefoxitin, clindamycin
Clostridium difficile	Metronidazole, vancomycin	Bacitracin
Gram-negative bacilli (BL negative)[a]	Penicillin	Metronidazole, clindamycin, chloramphenicol
Gram-negative bacilli (BL positive)[a]	Metronidazole, imipenem, a penicillin and β-lactamase inhibitor, clindamycin	Cefoxitin, chloramphenicol, piperacillin

[a] *Bacteroides fragilis* group; *Prevotella* spp., *Porphyromonas* spp., *Fusobacterium* spp.

BL, β-lactamase.

Penicillin and ampicillin, first-, second- and third-generation cephalosporins, and vancomycin are active against most gram-positive anaerobes but have unpredictable or little activity against most anaerobic gram-negative bacilli.[98,99] Penicillin derivatives, isoxazoyl penicillins, and nafcillin are considerably less active than penicillin G against most anaerobes. Many anaerobes possess cephalosporinases, and therefore, as a class, cephalosporins have limited utility. Approximately 85% of *B. fragilis* isolates are susceptible to cefoxitin, but the other *B. fragilis* group species are more resistant.[81] Cefotetan is less effective than cefoxitin against *B. fragilis* and other members of the *B. fragilis* group. Ceftriaxone, cefoperazone, and cefotaxime are not reliable enough against gram-negative anaerobes to be useful, and ceftazidime and cefepime have poor activity against both gram-positive and gram-negative anaerobes.[105] Vancomycin and daptomycin have good activity against many gram-positive anaerobes, but they have not been studied clinically.[106]

The macrolides have moderate to good in vitro activity against anaerobes other than the *B. fragilis* group and fusobacteria.[86] Macrolides are active against pigmented *Prevotella* and *Porphyromonas* spp. and microaerophilic streptococci, gram-positive non–spore-forming anaerobic bacilli, and certain clostridia. They are less active against *Fusobacterium* and *Peptostreptococcus* spp.[107,108] For penicillins, extended-spectrum penicillins, cephalosporins (excluding carbapenems), and chloramphenicol (for *B. fragilis*), minimal inhibitory concentrations effective against susceptible anaerobic bacteria are high (requiring use of maximal doses of agents), vary by inoculum size and other in vitro conditions, and cluster around breakpoints; these features all lead to interassay, interlaboratory, and interstudy variability in reports of percentage of resistant organisms. Tetracyclines and older fluoroquinolones have unreliable activity against anaerobes. Doxycycline and minocycline are more active than the parent compound.[82] Some broad-spectrum fluoroquinolones (gatifloxacin and moxifloxacin)[109] and tigecycline[110] have significant antianaerobic activity. The carbapenems (imipenem, meropenem, doripenem, and ertapenem) have excellent activity against most clinically relevant gram-positive and gram-negative anaerobes (including *Bacteroides* and *Prevotella* spp.) except *C. difficile.*[111]

Antimicrobial resistance of anaerobes has increased for clindamycin, cefoxitin, cefotetan, cefotaxime, and piperacillin. Anaerobic bacteria always have been resistant to aminoglycosides and trimethoprim-sulfamethoxazole. Resistant isolates have been recovered infrequently for the carbapenems, metronidazole, and the combinations of β-lactam and β-lactamase inhibitors.[75,82,112,113] The production of β-lactamase is the resistance mechanism of the *B. fragilis* group, as well as increasing numbers of other *Bacteroides, Prevotella, Porphyromonas,* and *Fusobacterium* spp.

Although susceptibility testing of isolates recovered from selected cases can provide information that affects management, therapy often is empiric and is based on knowledge of likely anaerobic and aerobic organisms, expected in vitro susceptibility, and pharmacodynamics of agents. Treatment of mixed infection should cover most aerobic and anaerobic pathogens.[73] Combination therapy is always required for intracranial abscesses (e.g., with penicillin or vancomycin plus metronidazole plus a third-generation cephalosporin) and for intra-abdominal infection (e.g., with metronidazole plus ampicillin plus cefepime or gentamicin).[102] Cefoxitin or ceftizoxime (neither of which is active against *Enterococcus* spp.), piperacillin-tazobactam, or a carbapenem if needed for expected gram-negative aerobes, could be used as monotherapy.[73] In a retrospective cohort study, monotherapy (piperacillin-tazobactam, meropenem, cefoxitin, or ceftriaxone) versus aminoglycoside-based triple-antibiotic therapy for children with ruptured appendicitis showed at least equal efficacy.[114] Nosocomial acquisition of infection affects antibiotic choice, especially to include agents with activity against expected or proven facultative or aerobic organisms.

Clostridium tetani (Tetanus)

Itzhak Brook

Tetanus is caused by a neurotoxin produced by *Clostridium tetani*. It is common in warmer climates. The worldwide incidence of tetanus is approximately 1 million cases annually. Although a major cause of morbidity and mortality in developing countries, tetanus is rare in the United States, with approximately 35 to 70 cases reported annually to the Centers for Disease Control and Prevention (CDC).[1] Reported cases are estimated to represent 60% of actual cases. Tetanus remains a likely diagnosis in certain clinical situations even in developed countries, and individual patients suffer severe morbidity. The decline in tetanus in developed countries is the result of an effective immunization program.

Most cases of tetanus occur in unvaccinated people and in adults; people older than 60 years of age account for 60% of the cases and for 75% of deaths from tetanus in the US. In the US, the current average annual incidence of tetanus is 0.1 cases/million and 0.023 cases/million among people ≥65 years of age.[1] The case-fatality rate is 13.2% overall but 31.3% in people ≥65 years of age. Approximately 15% of cases occur in diabetic patients or intravenous drug users. Approximately 75% of cases of tetanus in the US follow acute injuries, with less than one half of these injuries occurring outdoors. Chronic wounds and abscesses, wounds associated with a foreign body (e.g., splinters, thorns), surgical wounds, major trauma, parenteral drug abuse, and animal-related injuries are responsible for 25% of tetanus-associated injuries; approximately 20% of wounds are from unknown circumstances, and in 5% of cases of tetanus, no wound source can be identified. Rare causes of tetanus are burns and otitis media.[2]

Microbiology and Pathogenesis

C. tetani is a slender, gram-positive, nonencapsulated, motile, obligatively anaerobic bacillus that exists in vegetative and sporulated forms. The genome of the organism has been sequenced.[3] The sporulated form has a characteristic drumstick microscopic appearance because of the terminal position of spores. Spores are highly resistant to disinfection by chemicals or heat, but vegetative forms are susceptible to the bactericidal effect of heat (autoclaving at 121°C and 103 kPa [15 psi] for 15 minutes), to chemical disinfectants (iodine, glutaraldehyde, hydrogen peroxide), and to certain antibiotics.[4]

Spores are ubiquitous in soil and the gut of mammals; they are dormant and nonpathogenic in soil or contaminated tissue until conditions are favorable for transformation to the vegetative, pathogenic form. Such conditions are those of locally decreased oxygen reduction potential as created in devitalized tissue by a foreign body, trauma (especially crush injury), or suppurative infection.

C. tetani is noninvasive and does not cause an inflammatory response or tissue destruction. Disease is initiated by exotoxins. Two toxins are produced, tetanolysin (of uncertain importance) and tetanospasmin (a potent neurotoxin responsible for clinical tetanus). Tetanospasmin, often referred to as “tetanus toxin,” is encoded on a plasmid present in all toxigenic strains,[5] and it is released with growth of *C. tetani* at the site of infection. Tetanospasmin affects the neuromuscular end plates and the motor nuclei of the central nervous system, thereby causing skeletal muscle spasm and convulsions. Mechanisms of absorption and transport of tetanospasmin are not understood completely, but 2 mechanisms are speculated.[6] If a large amount of tetanospasmin is produced, spread to neurons through the bloodstream and lymphatic system occurs, causing spasm at sites distant from the site of infection that first affect muscles with the shortest neural pathway. Lockjaw and risus sardonicus, often seen in generalized tetanus, reflect this pathophysiologic process and are associated with rapidly progressive, severe disease. From the site of production, small amounts of neurotoxin also can ascend the neural axis (and sometimes the spinal axis cranially) to cause localized tetanus. The timing of onset of muscle involvement is proportional to the neural distance from the site of injury.

Tetanospasmin primarily gains access to the nervous system through the neuromuscular junction, where it migrates in retrograde fashion transsynaptically, protected from neutralizing antitoxin, to affect inhibitory synapses, where it prevents release of acetylcholine.[5] Uninhibited lower motor neurons increase tone of agonist and antagonist muscles, thereby causing characteristic localized spasms and rigidity.

Tetanospasmin also can prevent transmission at neuromuscular junctions and thus cause paralysis. The effect of the toxin on the brain is controversial; direct inoculation can cause seizures, but spasms of tetanus probably result from the spinal rather than the supraspinal action of tetanospasmin. Affected patients are fully conscious. Some clinical manifestations of tetanus suggest involvement of the sympathetic nervous system. The effect of tetanospasmin is permanent; recovery depends on ultrasprouting of neurons.

Clinical Manifestations

Tetanus is divided into clinical patterns that reflect host factors and the site of inoculation: generalized, localized, cephalic, and neonatal. In most cases, the site of injury, which often is minor, can be determined. Inability to identify a portal of entry does not exclude the diagnosis, especially in unimmunized people. The appearance of a wound is not helpful in diagnosis, but circumstances of occurrence are (e.g., severity of crush injury and soil contamination). In the US, most cases of tetanus occur after puncture wounds, farming or gardening activities,[2] or the use of illicit drugs.

The interval between the time of injury and the appearance of symptoms has important prognostic significance; the shorter the interval (<7 days), the worse the prognosis. The frequency and severity of clinical manifestations depend on the amount of toxin that reaches the nervous system. The portal of entry also is an important prognostic factor. Certain injuries (e.g., compound fracture, puncture wound in a drug user) or infections (e.g., that following abortion, infection of a neonate's umbilical stump, burn wound) have poor prognoses. Involvement of the autonomic nervous system portends a poor prognosis. Such data have been used to develop scoring systems to predict severity and prognosis.[5]

Generalized Tetanus

Generalized tetanus, which is a neurologic disease manifesting as trismus, dysphagia, and severe muscular spasms, is the most common manifestation of tetanus, usually occurring as a complication of localized tetanus that is recognized only in retrospect. The onset can be insidious over a period of 1 to 7 days. Trismus (lockjaw), the most common presenting symptom, commonly is mistaken as a manifestation of parapharyngeal infection or temporomandibular joint problems. A history of stiffness of the back or rigidity of the neck or abdomen frequently is recognized in retrospect. A subtle “sarcastic smile” (risus sardonicus) may be noticed, and rigidity of the abdominal muscles is detectable on examination.

As the disease progresses, additional muscle groups become involved, the most striking involvement being of the paraspinal musculature. The most dramatic feature of generalized tetanus is the very painful, generalized tetanic, opisthotonic spasm manifest as arching of the back (sometimes with just head and feet touching the bed) to resemble decorticate posturing (Fig. 188.1). The force can produce fractures of the vertebrae or other bones and hemorrhage into muscles. The periodicity of tetanic spells can cause confusion with seizures; however, patients with tetanus, unlike patients with seizures, do not lose consciousness. Spasms often are triggered by sensory stimuli. Respiratory compromise during tetanic spells can be life-threatening; upper airway obstruction is common, and with additional involvement of abdominal and diaphragmatic muscle, apnea can occur.

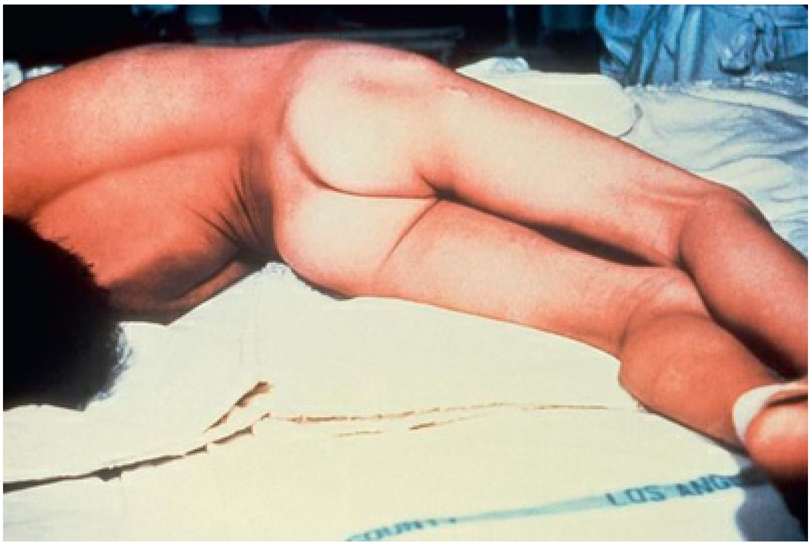

FIGURE 188.1 The patient is displaying opisthotonic posturing caused by *Clostridium tetani* exotoxin. (Courtesy of US Centers for Disease Control and Prevention.)

Symptoms of autonomic overactivity generally are manifest in early phases as irritability, restlessness, sweating, and tachycardia. In later phases, profuse sweating, cardiac arrhythmias, labile hypertension or hypotension, and fever commonly are present.[7] Episodes of bradycardia and hypotension can lead to cardiac arrest. Cardiac arrest also has been attributed to myocardial damage caused by the high catecholamine level,[8] as well as by toxic damage to the brainstem.[9] Fever can result from sympathetic overactivity or from superinfections, such as pneumonia.[10] Spasms and cardiovascular complications occur most commonly during the first week and resolve slowly during the ensuing 2 to 4 weeks.

Even with available treatment, generalized tetanus usually worsens in the first 2 weeks after diagnosis, with recovery occurring over the subsequent 3 to 5 weeks. If antitoxin is not given, disease persists for weeks to months until cessation of production and binding of tetanospasmin and the formation of new neuromuscular junctions.

Localized Tetanus

Localized tetanus is an unusual presentation. Muscles near the entry wound become painful and weak within 2 to 3 days after the injury and then become rigid; deep tendon reflexes are hyperactive. Rigidity usually persists for weeks to months and resolves spontaneously without progressing, although disease can progress to generalized tetanus.[11] Localized tetanus has a mortality rate <1%. In partially immune patients, neutralization of local toxin and heightened production of antitoxin can prevent generalized tetanus.

Cephalic Tetanus

Cephalic tetanus is a rare presentation, the result of decreased neuromuscular transmission of the lower cranial nerves affected because of wounds on the head and neck. Clinical manifestations usually occur 1 to 2 days after injury and can include facial palsy, dysphagia, paresis of extraocular muscles (ophthalmoplegic tetanus),[12] and supranuclear oculomotor palsies.[1,13] The mechanism of the last clinical manifestation is not clear. Usually, cephalic tetanus has a poor prognosis, although some patients have good outcome. Cephalic tetanus has been reported in patients after complete immunization. Cephalic tetanus can precede generalized tetanus.

Neonatal Tetanus

Neonatal tetanus is a generalized form of the disease that occurs only in infants born to inadequately immunized mothers. Tetanus usually follows infection of the umbilical stump, which can result from poor obstetric procedures, delivery outside a healthcare environment, inadequate postnatal care, or cultural practices such as application of cow dung or soil to the umbilical stump. Immunization of adolescent girls and women of childbearing age, appropriate training of midwives, and topical application of antibiotics can reduce the risk of neonatal tetanus. Neonatal tetanus is rare in developed countries but remains a significant problem in developing countries.[1,14]

Weakness and inability to suck are the most common manifestations, often appearing between 5 and 7 days of age (range, 3–24 days). Later, generalized tetanic spasms, rigidity, and opisthotonus occur (Fig. 188.2). The mortality rate is >90%, and death can be secondary to a hypersympathetic state. The major causes of death are apnea in the first week and septicemia in the second week, generally as a result of infection that originated at the umbilical stump. Other complications are pneumonia, pulmonary or central nervous system hemorrhage, and laryngeal spasm. Poor prognosis is associated with risus sardonicus, fever, age <10 days, and delayed presentation for medical care.[15]

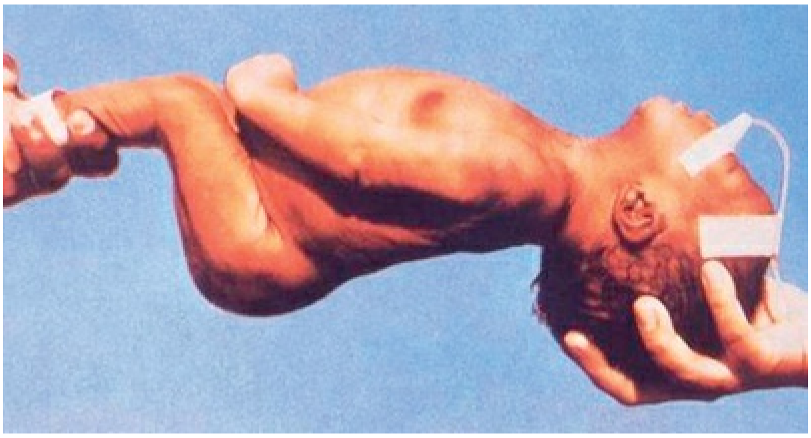

FIGURE 188.2 This infant with neonatal tetanus is displaying body rigidity produced by *Clostridium tetani* exotoxin. (Courtesy of US Centers for Disease Control and Prevention.)

Improvement is heralded by defervescence (usually within 3–7 days), decrease in the number of episodes of spasm, and slow resolution of rigidity. Complete resolution can take up to 6 weeks. Developmental disability often occurs in survivors.

Diagnosis and Differential Diagnosis

The diagnosis of tetanus is made from clinical findings in a setting of risk and by excluding other causes of tetanic spasms. Recovery of *C. tetani* from wounds is not helpful because the presence of this organism does not necessarily indicate toxin production. Laboratory tests are useful only to exclude other diseases; management cannot be delayed until test results are available. Although generalized tetanus and cephalic tetanus are recognized easily, the diagnosis can be unsuspected if no portal of entry is identified. Given the clinical suspicion, a history should be elicited regarding chronic otitis media, otitis externa, recent intramuscular injection, a minor surgical procedure, intravenous drug abuse, and rectal or vaginal instrumentation. Neonatal tetanus becomes apparent shortly after initial manifestations. Localized tetanus can be unrecognized until generalized manifestations occur. Trismus must be differentiated from manifestations of parapharyngeal and retropharyngeal infections.

The differential diagnosis of generalized tetanus includes stiff man syndrome,[16] pseudotetanus,[17] meningitis, encephalitis, hypocalcemic tetany, seizures, rabies, dystonic reactions to neuroleptic drugs or other central dopamine antagonists (for which treatment with an anticholinergic agent is rapidly effective), hysterical conversion reaction, and strychnine poisoning. Although strychnine poisoning is the most commonly confused intoxication, patients with such poisoning lack trismus and abdominal rigidity between spasms. Biochemical analysis of blood and urine for strychnine is performed in patients with suspected generalized tetanus. Conversely, tetanus always should be considered when strychnine poisoning is suspected.

Treatment and Outcome

The goals of management of tetanus are eradication of *C. tetani*, neutralization of toxin, and provision of specific supportive care.[18]

Providing aggressive, yet restrained, supportive care with a minimum of stimulation is challenging. Transfer to an optimal setting should be accomplished early in the disease, before the severity of spasms precludes moving the patient. Survival depends on minimizing morbid or fatal spasms over a prolonged period. The patient is protected from stimuli by isolation in a noise-free, darkened room, with a nurse in the room at all times, monitors silenced, and a sentry nurse positioned outside the door to limit entry and to reinforce minimal examination and manipulation of the patient.

The child with tetanus should be sedated, and human tetanus immune globulin (TIG) should be administered immediately. TIG neutralizes circulating tetanospasmin. Recommended dosage and administration of TIG are shown in Table 188.1.[19,20] Local infiltration of part of the dose around the wound is recommended. However, the efficacy of this technique has not been proven. In countries where TIG is not available, equine tetanus antitoxin (TAT) is an alternative. It is administered after adequate testing for sensitivity and desensitization if needed. Immune globulin intravenous (IGIV) can be given if TIG is not available.

TABLE 188.1

Treatment of Tetanus

Agent	Dosage and Administration
Tetanus immune globulin, human (TIG)	Single dose, 3,000–6,000 U IM[a]
Tetanus antitoxin (TAT)[b]	Single dose, 50,000–100,000 U after appropriate testing is performed for sensitivity and desensitization if necessary; part of dose (20,000 U) is given IV, and the remainder IM
Immune globulin intravenous (IGIV)	Single dose of 200–400 mg/kg IV can be considered if TIG is not available; not approved for this indication
Metronidazole	30 mg/kg/day (maximum, 4 g/day) divided into q6h doses PO or IV for 10–14 days
Penicillin G	100,000 units/kg/day (maximum, 12 million U/day) divided into q6h doses IV for 10–14 days
Tetracycline	25–50 mg/kg/day; an alternative; not approved for children <8 years old

[a] Some experts recommend a single dose of 500 units IM, which appears to be as effective and causes less discomfort.[14,15]

[b] TAT is not available in the United States; it should be used elsewhere only if TIG is not available.

IM, intramuscularly; IV, intravenously; PO, orally.

Local wound care is essential. Foreign bodies, if present, are removed; the wound is irrigated vigorously and debrided to remove devitalized tissue. Extensive debridement of puncture wounds is not needed. Excision of necrotic tissue may be required, but excision of the umbilical stump is no longer recommended in cases of neonatal tetanus.

C. tetani is susceptible to penicillins, cephalosporins, metronidazole, macrolides, tetracyclines, and imipenem.[21] Although the utility of antimicrobial therapy in tetanus is controversial, specific therapy should be given (see Table 188.1). Oral or intravenous metronidazole or parenteral penicillin G is appropriate. Oral tetracycline and intravenous vancomycin are effective against *C. tetani*, but the cephalosporins are not reliably active. When a polymicrobial infection is present, broad antimicrobial coverage may be necessary.

A single, nonblinded clinical study performed in Indonesia compared oral metronidazole with intramuscular penicillin for treatment of tetanus.[22] Patients treated with metronidazole had less progression of disease (i.e., severity and frequency of spasms), shorter hospital stays, and better overall survival rates. The validity of these findings may have been compromised by an inadequate dose of penicillin given intramuscularly, the administration of which can increase the severity and frequency of tetanic spasms. Although theoretically penicillin could act synergistically with tetanospasmin to worsen neuromuscular effects,[23] extensive experience has been accrued for penicillin treatment of tetanus.[24]

Sedation and muscle relaxation in patients with mild cases should be accomplished, generally with diazepam, 0.1 to 0.2 mg/kg given intravenously every 4 to 6 hours. Ventilatory assistance is imperative at higher doses. Other benzodiazepines (lorazepam or midazolam) are equally effective. Additional sedation with a phenothiazine drug is appropriate; use of phenothiazine alone is less effective than sedation with diazepam. If spasms are not controlled effectively, therapeutic paralysis is necessary. Neuromuscular blockade can be achieved with curariform drugs. The agents used most often are pancuronium and vecuronium.

Suppression of excessive catecholamine release (which induces the autonomic dysfunction) can control the dysautonomia. Labetalol (0.25–1.0 mg/min) frequently has been administered because of its dual α- and β-blocking potential. β-Blockade alone (i.e., with propranolol) should be avoided because of the danger of sudden death.[25] Morphine sulfate (0.5–1.0 mg/kg/hr by continuous intravenous infusion) is used commonly to induce sedation and to control autonomic dysfunction by reducing sympathetic tone in the heart and the vascular system, thus controlling cardiac instability without causing cardiac compromise.[26] Other agents available for the treatment of various autonomic events are atropine, clonidine, and epidural bupivacaine.[27]

Of the foregoing drugs only magnesium sulfate was evaluated in a randomized clinical trial,[28] as well as in clinical series for controlling spasms.[29–32] The results of these studies brought about the use of magnesium titrated to clinical end points as a first-line agent in the management of tetanus. Magnesium is a vasodilator, and it reduces catecholamine release from the adrenal medulla[33] and adrenergic nerve endings.[34]

In a randomized, double-blind study of 256 patients, magnesium sulfate infusion (loading dose 40 mg/kg over 30 minutes, followed by continuous infusion of 2 g/hr for patients >45 kg or 1.5 g/hr for patients ≤45 kg) was compared with placebo.[28] Magnesium sulfate significantly reduced the need for other drugs to control muscle spasms, and patients were 4.7 times (95% confidence interval, 1.4–15.9) less likely to require verapamil to treat cardiovascular instability than were subjects in the placebo group.

Hypotension, if present, is treated initially with saline solution; if hypotension remains unresolved, a pulmonary catheter is placed for monitoring, and fluid, dopamine, or norepinephrine is administered as indicated.

Nutritional support should be initiated as soon as possible to sustain the patient's high caloric and protein needs. Enteral feeding is preferred; a percutaneous endoscopic gastrostomy tube is used commonly to limit gastroesophageal reflux compared with a nasogastric tube. Prevention of thromboembolism can be attained with heparin, low-molecular-weight heparin, or other anticoagulants, and it should be begun early. Because patients often become disabled because of the drug-induced paralysis and immobilization, physical therapy should be initiated as soon as spasms have abated.

Complications of tetanus are shown in Table 188.2.

TABLE 188.2
Complications of Tetanus

Complications	Comments
Cardiomyopathy	Direct toxic effect
Phrenic nerve palsy	Direct toxic effect
Laryngeal nerve palsy	Direct toxic effect
Respiratory compromise	Secondary to spasms
Rhabdomyolysis	Secondary to spasms
Myositis ossificans circumscripta	Secondary to spasms
Vertebral compression fracture	Secondary to spasms
Hypoxic cerebral injury	Secondary to respiratory compromise
Acute renal failure	Secondary to rhabdomyolysis
Psychological effects	Most prominent after recovery

Prevention

No reliable natural immunity to tetanus exists. Prevention consists of providing neutralizing antibody to tetanospasmin in case *C. tetani* contaminates and multiplies in a wound.

Primary Prevention

Primary prevention is pre-exposure immunization, consisting of primary immunization followed by booster doses of tetanus toxoid–containing vaccines (TT) throughout life.[35] Schedules are shown in Table 188.3.[36] The goal of immunization is to provide a continuous serum concentration of 0.01 IU/mL of neutralizing antitoxin.[37,38] Protection between levels of 0.01 and 1.0 IU/mL is not absolute; some authorities consider an antibody level of 0.15 IU/mL or greater as protective.[39]

TABLE 188.3

Prevention of Tetanus

PRIMARY IMMUNIZATION[a]				
Age	**Vaccine**			
2 mo	DTaP			
4 mo	DTaP			
6 mo	DTaP			
12–18 mo	DTaP			
4–6 yr	DTaP			
≥11–12 yr	Tdap once			
Every 10 yr (booster)	Td			
SECONDARY IMMUNIZATION[b]				
History or Dose of Tetanus Toxoid Administration	**Clean Minor Wound**		**All Other Wounds**[c]	
	TIG	**Td**[d]	**TIG**	**Td**[d]
<3 doses or unknown	No	Yes	Yes	Yes
≥3 doses[e]	No	No[f]	No	No[g]

[a] If an infant has contraindications to pertussis vaccine, diphtheria and tetanus toxoids (DT) are given on the same schedule; if primary immunization is begun at 7 years, Td/Tdap is used (see Chapter 162).

[b] See text for important details.

[c] Such as, but not limited to, the following: wounds contaminated with dirt, feces, soil, or saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.

[d] For children <7 years old, DTaP (DT if pertussis vaccine is contraindicated) is preferred to tetanus toxoid alone; for persons >7 years old, Td is preferred to tetanus toxoid alone. For children and adolescents, Tdap should be used when Td is indicated if the patient has not already received Tdap.

[e] If the patient has received only 3 doses of fluid toxoid, a fourth dose of toxoid, preferably an adsorbed toxoid, should be given.

[f] Yes, if >10 years since last dose.

[g] Yes, if >5 years since last dose (more frequent boosters are not needed and can accentuate side effects).

DTaP, diphtheria and tetanus toxoids and acellular pertussis; Td, tetanus and diphtheria toxoids; Tdap, tetanus and diphtheria toxoids and reduced acellular pertussis; TIG, tetanus immune globulin.

Several longterm follow-up studies indicated that protective antitoxin levels persist in 91% to 96% of people 10 years after receipt of the initial 3-dose series of TT as infants.[40–42] In 1 study, 70% of the subjects >6 years of age and living in the US had antibody levels ≥0.15 IU/mL.[43] The presence of protective antibody dropped with age from >90% in children 6 to 9 years of age to 80% in children 10 to 16 years of age, to <28% in adults ≥70 years of age. Rates of seronegativity reflect the time since immunization or the lack of immunization.

Immunodeficient people may not acquire adequate response to TT and require passive immunization. Stem cell or bone marrow transplant recipients must be revaccinated with at least 2 doses.[44] In 1 study, although only 38% of human immunodeficiency virus–infected children and adolescents had protective tetanus antibody levels, most developed and maintained protective levels after booster administration.[45] Severe anaphylactic reactions, brachial neuritis, and Guillain-Barré syndrome following TT administration have been reported rarely.

Secondary Prevention

Secondary prevention consists of administration of vaccine and antitoxin (TIG) after a tetanus-prone injury (see Table 188.3), with the need determined by the type of injury and the patient's immunization history. Although wounds with major tissue injury are most tetanus prone, any type of wound, if contaminated, can lead to tetanus.[14] Immunization is given immediately if the patient's tetanus immunization history is not available or is uncertain or if 60 months or more have elapsed since the last TT booster dose. When indicated by immunization history, TIG is given intramuscularly in a dose of 250 units (regardless of age or weight). Immune globulin intravenous or equine tetanus antitoxin is recommended if TIG is unavailable. Decisions on the need for TIG for infants <6 months of age who have not received a full 3-dose primary vaccine series should be based on the mother's TT immunization status at the time of delivery. Additional circumstances warrant the use of TIG in immunized people, including anticipated impairment of response to vaccine, and in certain wounds, such as major burns, frostbite, crush injury, or injury by avulsion, puncture, or missile.

Hyperimmunization (multiple booster doses of toxoid over a short time) can cause severe local reactions at the injection site, such as swelling of the entire arm. Patients with such reactions have high antitoxin levels.[46] Preformed antitoxin forms complexes with administered toxoid and induces an Arthus type II hypersensitivity response. The use of tetanus toxoid in situations where it is not indicated is inappropriate.

Tertiary Prevention

Tertiary prevention consists of antitoxin and immunization given after clinical tetanus is manifest. Tetanus does not provide protective immunity, probably because the minute amount of toxin produced is insufficient to elicit an immune response.[47] All patients should complete a series of immunizations with tetanus toxoid, beginning at presentation.

Clostridium botulinum (Botulism)

Sarah S. Long

Botulism is a neuroparalytic disease caused by the action of a heat-labile neurotoxin produced almost exclusively by *Clostridium botulinum.* Botulism is categorized by modes of acquisition: (1) *foodborne botulism,* which results from the ingestion of preformed toxin elaborated in food that was naturally contaminated with spores and improperly preserved; (2) *infant botulism,* which results from intestinal colonization, outgrowth, replication, and toxin elaboration after the ingestion of spores; and (3) *other,* which includes wound botulism resulting from contamination of wounds with spores, outgrowth, and toxin elaboration; adult intestinal toxemia botulism resulting from intestinal colonization and in vivo toxin production, usually in the context of abdominal surgical procedures, gastrointestinal tract abnormalities, and recent antibiotic treatment; and accidental botulism resulting from high-dose injection of toxin for treatment of muscular movement disorders or injection of an unlicensed product for cosmetic purposes.[1–5]

Since recognition of infant botulism in 1976, approximately 3300 cases were reported in the United States through 2014. Although the US reports 90% of botulism cases worldwide, cases have been reported from every continent except Africa.[6] Infant botulism is the most common form of botulism, accounting for approximately 75% of all US cases, with a mean of 112 cases annually from 2001 through 2014.[7] Increase in cases over time may be real or related to increased awareness (Fig. 189.1). Infant botulism is the primary focus of this chapter.

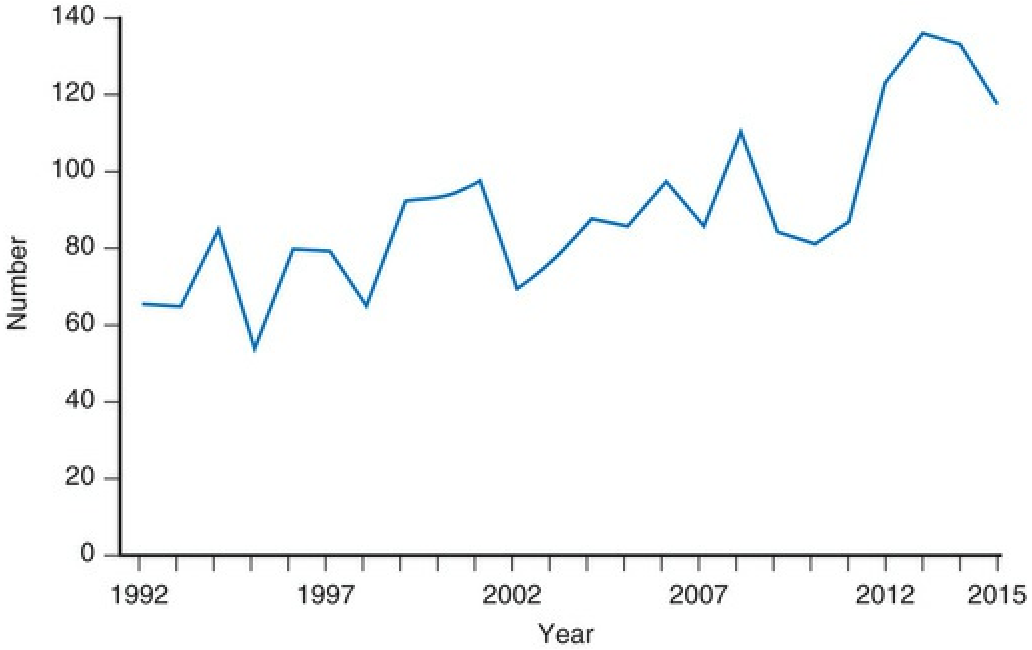

FIGURE 189.1 Number of reported cases of infant botulism by year in the United States from 1992 to 2015. Cases numbers for 2015 are provisional. (Redrawn from data from the National Notifiable Diseases Surveillance System in Centers for Disease Control and Prevention. Summary of notifiable diseases—United States, 2012. MMWR Morb Mortal Wkly Rep 2014;61:1–55.)

Etiology and Pathogenesis

Organisms and Toxins

C. botulinum represents a heterogeneous group of gram-positive, anaerobic, spore-forming bacilli, individual strains of which can produce 1 of 7 serologically distinctive neurotoxins (BoNT) types A through G. More than 98% of cases of infant botulism in the US are caused by BoNT/A or BoNT/B; rare cases cause by BoNT/C,[8] BoNT/E,[9–11] BoNT/F,[11,12] and BoNT/G[13] are reported in the US or elsewhere. *Clostridium butyricum*[10,11] is responsible for rare cases caused by BoNT/E, and *Clostridium baratii* is responsible for BoNT/F cases of infant botulism in neonates.[12,14,15] Clinical cases occasionally demonstrate mixed toxin types and are designated by primary toxin and secondary toxin, (e.g., BoNT/Ba or BoNT/Af).

Unexpressed botulinum toxin genes can be found in a variety of clostridial species, and more than 1 toxin type can be found in a single *C. botulinum* strain.[16,17] Amplified fragment length polymorphism (AFLP) analysis of a national collection from cases and related environmental samples showed 154 clades and co-location of clades between individual cases and their environment (with 52% of isolates clustered in 2 clades). A single clade could be associated with a spectrum of case severity.[6]

After systemic absorption, BoNT is concentrated at the plasma membrane of the neuron, and it is taken into the synaptic vesicle where it binds irreversibly to receptors on presynaptic cholinergic and adrenergic nerve endings; a portion is internalized, cleaving synaptosomal-associated protein of 25 kd (SNAP-25) and shutting down the neuroexocytosis apparatus within the cell and acetylcholine release.[13,18] With intoxication at 70% or more junctions, clinical voluntary muscular and autonomic function is impaired; with intoxication at 90%, diaphragmatic muscular function is impaired. Recovery depends on the 30-day regeneration of SNAP-25. Neutralizing antitoxin effectively binds toxin only before internalization of the toxin molecule. *C. baratii* BoNT/F cleaves synaptobrevin, which in a rat model has a 7-day regeneration time.[12]

Botulinum toxins are similarly structured, large, single polypeptides and are the most potent toxins known; 10^{11} molecules (0.3 ng) reaching neuromuscular junctions are enough to cause clinical botulism. BoNT/A is the most avidly binding and potent toxin and is associated with the most severe disease. BoNT is acid and enzyme resistant but can be destroyed by heating of food to the boiling point (100°C) for 10 minutes. Certain environmental conditions, such as anaerobic conditions, pH >4.6, warm temperature (>39°C), and high moisture content, promote outgrowth of spores to vegetative forms and production of toxin in food. Spores of *C. botulinum* are heat resistant, withstanding 100°C for hours; food must be heated under pressure to temperatures of 116°C to destroy spores.

Pathophysiology

In more than 90% of cases in the US, infant botulism results from unrecognizable ingestion of botulinal spores from dust. Since the recommendation to avoid feeding honey to infants,[2,4,5] infant botulism has been infrequently associated with honey, but honey still is a significant source of spores for cases in other countries.[9,19,20] The gastrointestinal tract of children and adults is resistant to outgrowth of *C. botulinum* spores, but in infants younger than 12 months of age occasionally it is permissive of such outgrowth. Age-related vulnerability is related at least partially to lack of competitive flora and possibly to pH and motility. Experimentation and observation in a mouse model provided compelling evidence of the importance of competitive flora in protection, such as the following: (1) age-limited (7–13 days) natural susceptibility to intestinal colonization by *C. botulinum* spores; (2) ongoing susceptibility in germ-free adults; (3) acquisition of resistance in germ-free adults after replacement in a normal cohort colony for 3 days; (4) resistance after establishment of selective, limited intestinal flora; and (5) loss of resistance after antibiotic suppression of intestinal flora.[21,22]

The necessary components of resistance are undoubtedly complex, but *Bacteroides, Lactobacillus,* and other *Clostridium* spp. are inhibitory to *C. botulinum.* Stool flora of 7 infants delineated at first manifestations of botulism showed a relative paucity of *Bacteroides* and *Lactobacillus* spp.[23] The putrefactive intestinal flora of the infant who is fed formula and the fermentative flora of the infant who is fed human milk would be expected to be inhibitory. Epidemiologic data support the theory that the period of permissiveness of the gut of the infant fed formula is brief (i.e., competing flora is established rapidly[24]), and that of the infant fed human milk is more extended and is especially heightened during perturbation of flora during weaning.[25] Infant botulism is more often associated with feeding of formula in infants <1 month of age, but by 4 months of age almost 100% of infants with cases are fed human milk.[26] The natural occurrence of infant botulism in horses (shaker foal syndrome) and ducks (limberneck) suggests a similar age-related vulnerability to colonization in animals. The rare cases of intestinal toxemia botulism in older persons almost always have been associated with an underlying gut anomaly[3] or a presumed alteration of gut flora, pH, or motility by surgical procedures and drugs.[27]

Epidemiology

Environmental Exposure

Potential sources of *C. botulinum* spores are the environment and naturally contaminated foodstuffs. *C. botulinum* spores are ubiquitous worldwide, found in cultivated and virgin soil, in aquatic sediment and marine life, and in the intestinal content of birds. *C. botulinum* strains producing BoNT/A, BoNT/B, and BoNT/F generally are found in areas of low rainfall and moderate temperature, whereas those producing BoNT/D and BoNT/E are associated with water.[9,28] In the most recent soil survey in the US performed in 1975, 23% of soil samples contained botulinal spores, and *C. botulinum* spores producing BoNT/A, BoNT/B, BoNT/C, BoNT/D and BoNT/E were found.[29] In the US almost all *C. botulinum*-producing BoNT/A spores are found west of the Mississippi River, where the Rocky Mountain cordillera rise out of the Middle and Great Plains (Fig. 189.2). BoNT/B spores have a more general east-west distribution but are confined almost totally to areas between 35 and 55 degrees of north latitude and occur in soil with high organic content. BoNT/E spores are found in marine life and sediment around fresh water from the Pacific northwest and the Great Lakes region of the US,[9,28] and *C. botulinum* BoNT/F spores have been isolated from marine sediment from the Pacific coast and from crabs in the Chesapeake Bay. The reasons for the geographic distribution of *C. botulinum* that produce different neurotoxins largely are unknown. Soil sampling in Argentina showed that 23% of samples were positive for a variety of *C. botulinum* types; the distribution was uneven, with a higher prevalence in cultivated soil.[30]

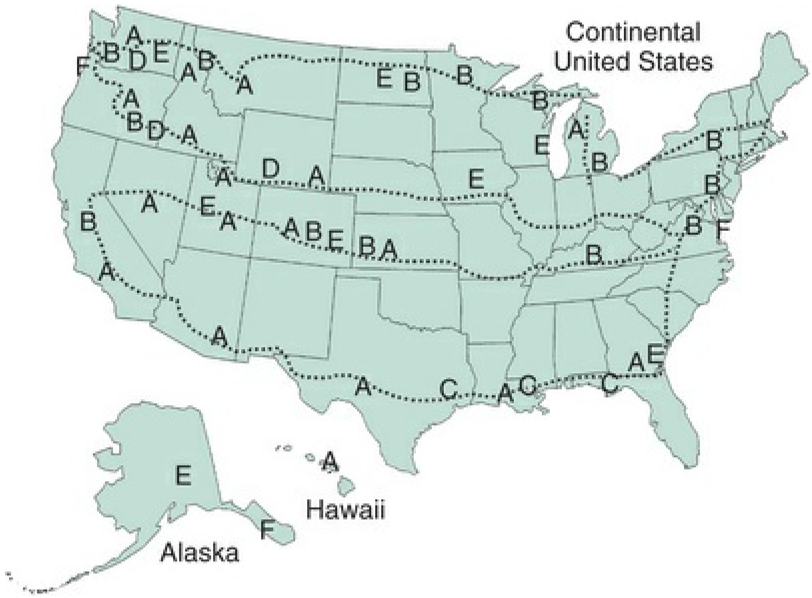

FIGURE 189.2 **Natural occurrence of *Clostridium botulinum* spores by toxin type. Data primarily represent 4 east-west crossings of the United States (dotted lines) during which soil samples were collected every 50 miles. Multiple samplings were positive in some states (not shown).**

(Data from Smith LD. The occurrence of *Clostridium botulinum* and *Clostridium tetani* in the soil of the United States. Health Lab Sci 1978;15:74–80.)

The geographic distribution of *C. baratii*–producing BoNT/F is less certain because the organism would not be detected by microbiologic screening for *C. botulinum;* the source was thought to be the environment in cases of infant botulism from California and Iowa, and the environment or contaminated food in adults, but the source of *C. baratii* botulism has not been proved.[13,15,31–34]

Botulism case density and toxin types in humans (and animals) mirror the geography and density of *C. botulinum* spores in the environment. Infant botulism undoubtedly is underrecognized, but cases have been reported from all continents except Africa and from all states in the US.[35] The highest reported incidence of disease in the US is the Delaware–Pennsylvania–New Jersey region arching Philadelphia, followed by California and Utah.[7] Argentina, Australia, Canada, Italy, and Japan, respectively, have reported the next largest numbers of cases.[35]

Among US cases of infant botulism overall, approximately one half are caused by BoNT/A and one half by BoNT/B, with rare cases usually caused by to BoNT/F or BoNT/E. Cases in California are divided between BoNT/A and BoNT/B,[36] but BoNT/B accounts for >90% of cases in Pennsylvania.[23] One or more samples from an affected infant's environment, such as yard soil, vacuum cleaner dust, crib, father's shoes, or consumed honey, usually will yield *C.*

botulinum spores, always of matching toxin type.[23,36] Samples do not contain preformed toxin.

Unusual epidemiologic findings also suggest uneven distribution of spores within limited geographic areas. In 1 Pennsylvania study, residences of 83% of the 53 patients with botulism formed an arc around Philadelphia, with remarkable sparing of the city itself, counties surrounding the arc, and the western parts of the state.[25] In Colorado, 3 of only 6 cases reported between 1977 and 1985 were from the same town of 800 people; 2 of 3 infants shared a crib (years apart), and all samples from their environments (including the crib) yielded *C. botulinum*–producing BoNT/A.[37] Nearly all of 39 infants with botulism in Utah over a 20-year period resided within a 70-mile metropolitan corridor including Salt Lake City, Ogden, and Provo.[38] A cluster of 12 cases occurring over 2 years in Utah suggested an association with wind and rain[39]; such a correlation was not found in Pennsylvania.[23]

Many parents of infants with botulism report nearby soil disruption (e.g., home or commercial construction or road work) or a dusty “event” before the onset of the infant's illness.[23,39] Nearby construction was common but was not significantly associated with botulism in a prospective case-control study performed by the US Centers for Disease Control and Prevention (CDC).[26] In Pennsylvania, 50% of the infants' fathers had occupations that required daily contact with soil; on testing, spores were found on work shoes or at a work site in most cases.[23] Organisms of matching toxin type were found in yard soil and drinking water in cases in Australia,[40] as well as in vacuum cleaner dust in a case in Finland.[41]

In the 1970s and 1980s, honey and light and dark corn syrups were found to harbor *C. botulinum* spores and tested positive in 0.5% to 20% of samples.[42,43] Following changes in corn syrup production, the Food and Drug Administration (FDA) laboratory found that samples tested negative for *C. botulinum*.[44] Corn syrup has not been a proven vehicle for spores in any case of infant botulism and can be given to young infants safely. Consumption of honey is a clear risk factor for infant botulism (odds ratio [OR] = 9.8 in 1 study),[30,34] but because of avoidance, honey accounts for <5% of cases currently in the US. A case of infant botulism BoNT/B in the United Kingdom was linked to isolation of *C. botulinum* spores from powdered infant formula[45,46]; nonbotulinal clostridial spores have been found in commercial powdered formula in the US, a finding suggesting potential vulnerability of this foodsource.[47] A few cases of infant botulism have been linked to unusual environmental sources, for example, 2 BoNT/E cases in Ireland related to pet terrapins or terrapin feed,[48] BoNT/B related to chamomile and fennel infusion in Spain,[49] and BoNT/Ab related to well water in Japan.[50]

Host Susceptibility

Infant botulism has both a striking age group for susceptibility and an association with feeding. The youngest reported patient had an onset of disease at 38 hours of age,[30] and the oldest had an onset at 11.7 months.[26] More than 90% of cases occur between 6 weeks and 6 months of age. The median age at onset of infant botulism is significantly earlier in infants fed formula (7.6 weeks) than in infants fed human milk (13.7 weeks).[23,39] The age at onset of BoNT/F (caused by *C. baratii*) and BoNT/E (caused by *C. butyricum*) is <14 days of age, which is significantly younger than the median age of 84 days for BoNT/A or BoNT/B.[12,14,15,31–33] Breastfeeding is a clear risk factor for infant botulism, present in 66% to 100% of cases in published series.[23,26,27,39] Breastfeeding was not a risk factor for infants with disease before 2 months of age in 1 study, and it appeared to be protective against a rapidly fatal course.[26] Long and colleagues[23] found that 66% of breastfed infants with botulism who had received human milk exclusively had introduction of the first nonhuman food substances (cereal, formula, fruit) within 2 to 4 weeks before the onset of symptoms.

Many sociodemographic and racial factors associated with infant botulism probably are markers for breastfeeding. Additional age-specific risk factors were living in a rural or farming area for infants younger than 2 months (OR = 6.4) and having less than 1 bowel movement per day for at least 2 months (OR = 2.9) for older infants.[26] Fig. 189.3 is a schematic summary of environmental factors, host factors, and pathophysiologic events in infant botulism.

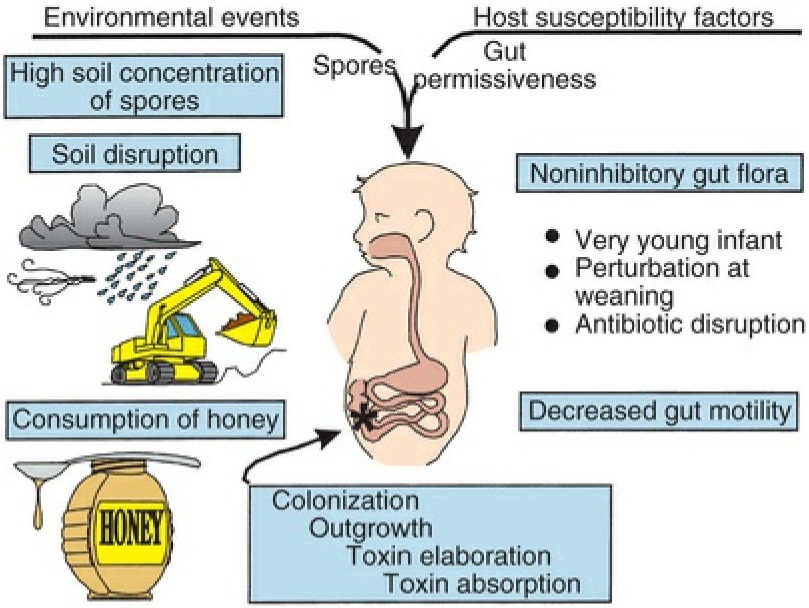

FIGURE 189.3 **Environmental, host, and pathophysiologic events in infant botulism.**

Immunity

C. botulinum is not part of the normal intestinal flora. No apparent natural acquisition of immunity to the organism or its toxin occurs. Infants recovering from botulism have a continued presence of organisms and toxin in stool for weeks to months.[51] These infants develop demonstrable specific serum antibody to toxin, the extent and duration of protective effect of which is not known.[52] Cases of relapsing hypotonia within weeks of hospital discharge in untreated infants have been reported, but no distant recurrences; occurrence after 12 months of age is rare in all people.

Clinical Manifestations

The clinical manifestations of botulism are similar regardless of the mode of acquisition. The spectrum of infant botulism is broad, with sudden infant death syndrome (SIDS) an occasional presentation at one extreme and transient mild weakness and hypotonia, slow feeding, or constipation alone at the other. Clinical manifestations have not changed over 4 decades of discovery.[5,39]

Classic Manifestations

After an unknown incubation period, symptoms of descending symmetric paralysis progress over 6 hours to 20 days (median, 4.2 days) before medical recognition or hospitalization.[23] Cranial nerves are affected first, with a subtly flat facial expression, quiet voice, and less avid suck—usually noted only by parents. The relative frequency of symptoms and signs is shown in Table 189.1.[23,38,39,53,54] Decreased frequency of bowel movements, floppiness, poor feeding, gurgling, and drooling are noted almost universally by the time of hospitalization.

TABLE 189.1

Symptoms and Signs at the Time of Hospitalization in 251 Infants With Botulism

Finding	Percent Occurrence Across Studies	
	Average (%)	Range (%)
HISTORY		
Decreased bowel movements	83	65–100
Poor feeding, weak suck	92	79–100
Floppiness, weakness	93	88–100
Weak cry	65	18–100
PHYSICAL EXAMINATION		
Temperature ≥38.3°C	14	—
Decreased spontaneous movement	82	—
Decreased phonation	80	—
Poor head control	97	96–98
Ptosis	84	75–97
Sluggish pupils	55	50–79
Ophthalmoplegia	55	18–61
Facial weakness	75	69–84
Decreased gag reflex	89	75–100
Difficulty swallowing	90	75–92
Hyporeflexia	54	52–57
Absence of reflexes	6	0–7
Flushed robust appearance	18	—
Decreased tears or saliva	18	18–79

Data from references 23, 38, 39, 53, and 54 (not all findings were reported in all studies).

The physical examination is most notable for the infant's quiet, still demeanor. Poor head control and hypotonia (inability of sustained postural control and movement against gravity) are universal. Although frequently misinterpreted as “lethargic” and “septic,” the infant is alert but rendered (by motor weakness) unable to smile, regard, vocalize, or move; skin color is normal or robust (Fig. 189.4). The diagnosis should not be made in the absence of head lag and cranial nerve palsies as first neurologic manifestations; swallowing function is most affected, and corneal reflexes are most preserved. Disconjugate gaze precedes ophthalmoplegia. Pupils become dilated or sluggishly reactive. Hyporeflexia is unimpressive early in the course relative to profound hypotonia, but it progresses over time. Respiratory difficulty is present in <20% of patients at hospitalization, but it is variable by case, age, and promptness of diagnosis.

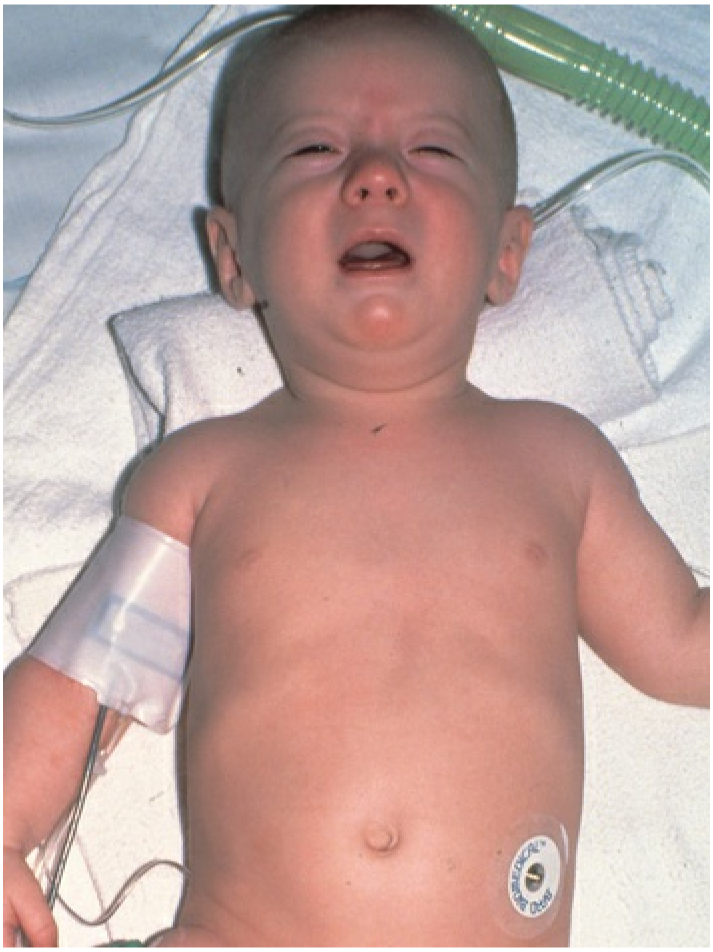

FIGURE 189.4 A 3-month-old infant with botulism just before intubation. Note bilateral ptosis and facial palsy and the absence of tears.

Autonomic dysfunction is underrecognized. Decreased tearing and salivation can be misinterpreted as dehydration. Erythema of oral mucosa can be misinterpreted as pharyngitis. Blood pressure, heart rate, and skin tone fluctuate frequently. Harlequin flushing can occur. Decreased intestinal motility, poor anal sphincter tone, and bladder atony are present commonly. No abnormality of sensation occurs.

Infants Younger Than 2 Months of Age

Progression is most rapid and severe in infants younger than 2 months of age.[26,55] Hypotonia leads rapidly to an inability to protect the airway and collapse of hypopharyngeal support, which can manifest within hours of the appearance of subtle clues of poor feeding or muscle weakness, or it can be the sentinel event. Very young infants with *C. baratii* BoNT/F have rapid progression to respiratory failure and have not had heralding constipation.[12,31]

Sudden apnea, fulminant paralysis, a brief resolved unexpected event (BRUE), or sudden infant or unexpected death syndrome (SIDS/SUDS)[55] can occur in young infants with botulism. Arnon and colleagues[56] proposed a significant association by the age of epidemic curves of botulism and SIDS, and they further associated the SIDS presentation of botulism with formula feeding (and possibly iron fortification). Spika[26] found that the severity of botulism in infants younger than 2 months of age was unrelated to feeding. In 2 studies, *C. botulinum* was isolated from intestinal contents in 4%[56] and 15%[13] of SIDS cases; in the latter study performed in Switzerland, unusual toxin types, such as BoNT/C, BoNT/F, and BoNT/G, were identified.[13] A prospective study in Australia failed to confirm the presence of *C. botulinum* in 248 victims of SIDS.[57]

Differential Diagnosis

Several disorders associated with weakness or hypotonia can mimic infant botulism superficially,[58,59] but the constellation of findings in the setting of age, feeding history, and exposures usually is classic, and the possibility of another diagnosis is remote. In the approximately 5% of infants treated empirically for botulism that was not confirmed in 1 report, multiple conditions were responsible, especially metabolic disorders, neurologic conditions, and spinal muscular atrophy.[58] Table 189.2 shows differentiating features of conditions frequently considered.[59] Tick paralysis (rare in infants) causes symmetric ascending flaccidity, with gait abnormality the usual first manifestation. In the Miller Fisher variant of Guillain-Barré syndrome (rare in infants), ataxia and areflexia occur early in the course of ophthalmoplegia. In a case of a 9-week-old infant with botulism, biopsy for possible Hirschsprung disease was performed because of constipation before neurologic abnormalities were noted.[60]

TABLE 189.2

Differentiating Features of Conditions Considered or Misdiagnosed in Infants With Botulism

Conditions	Expected Findings
Septicemia	Fever, lethargy, mottling
Meningitis or encephalitis	Fever, irritability, nuchal rigidity; specific or predominant CNS abnormalities; abnormal CSF
Cerebrovascular event	Focal neurologic deficits; abnormal CT or MRI
Genetic metabolic disorder	Onset with vomiting, irritability, or intellectual or neurologic abnormality; no weakness
Hypothyroidism	Hypotonia, lethargy, poor development; onset over weeks to months
Myasthenia gravis	Neonatal, or older age at onset; ptosis usually sole finding early
Spinal muscular atrophy	Inherited, progressive hypotonia and weakness; involvement of tongue, face, jaw, with sparing extraocular muscles and sphincters; areflexia
Anticholinergic poisoning	Agitation, coma, extrapyramidal movements
Polio-like condition or AFP	Asymmetric, spotty paralysis; aseptic meningitis; spasms
Guillain-Barré syndrome	Rare before 2 years of age; progressive symmetric ascending paralysis; areflexia; CSF proteinosis

AFP, acute flaccid paralysis; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; MRI, magnetic resonance imaging.

Diagnosis

Results of routine laboratory tests are normal (i.e., complete blood count, erythrocyte sedimentation rate, and cerebrospinal fluid values). Definitive diagnosis requires detection of the toxin in stool by mouse bioassay; the test result is positive in all likely cases of infant botulism when an adequate specimen is obtained. Assays are available through state health department laboratories or the CDC. Polymerase chain reaction testing usually is used to screen foodstuffs or to focus the neutralization part of the mouse bioassay.[16,61] *C. botulinum* organisms and toxin routinely are recoverable from stool of affected infants for weeks, and recovery is reported for as long as 7 months.[51]

Isolation of Organisms

Culture is performed only in special circumstances. *C. botulinum* can be isolated from stool, intestinal contents from autopsy specimens, wound, food specimens, or dust or dirt with the use of enrichment in chopped meat broth and then anaerobic incubation on selective egg yolk agar. Specimens for culture should be refrigerated if inoculation is not prompt. Density of organism in stool can be as high as 10^8 colony-forming units/g. *C. botulinum*–producing BoNT/A through BoNT/F produce lipase, which is detected as an iridescent film surrounding colonies. Vegetative cells are straight or slightly curved, motile, gram-positive bacilli with oval subterminal spores. Identity is confirmed by carbohydrate fermentation, biochemical reactions, and gas chromatography; typing is assigned according to toxin production by using mouse toxin neutralization assay or PCR assay.

C. botulinum–producing BoNT/G, *C. butyricum* BoNT/E,[11] and *C. baratii* BoNT/F[4,59] are lipase negative and may not be detected by usual screening and isolation techniques. *C. botulinum*–producing BoNT/G also is asaccharolytic. Isolation of *C. botulinum*–producing BoNT/E from the stool of an affected infant was successful only after enrichment following identification of the toxin gene by PCR testing of culture supernatant.[9]

Identification of Toxin

Bioassay performed on sterile stool filtrate is the only reliable confirmatory test for infant botulism. Passed stool is the preferred specimen for bioassay, but effluent obtained after a small-volume enema using sterile, nonbacteriostatic water is acceptable. In the latter instance, subsequent specimens are collected if the initial test result is negative and the diagnosis is likely. Specimens for assay should be refrigerated but not frozen pending shipping directions from public health officials. Serum assay results are positive in <10% of infants with botulism, and implicated honey does not have preformed toxin.

Neurologic Tests

Electromyographic findings characteristic of botulism are (1) motor unit action potentials of brief duration and small amplitude that are overly abundant for the amount of stimulus (so-called BSAP pattern), (2) enhancement of compound action potential in response to rapidly repetitive nerve stimulation at 30 Hz, (3) normal velocity of nerve conduction, and (4) no significant clinical response to injection of edrophonium chloride or neostigmine. Findings of electromyography depend on the stage of disease and the timing and amount of nerve stimulation. Because the age and clinical findings are unique and the diagnosis can be proved by toxin assay, painful electromyography usually is not justified; this study provides no prognostic information. An edrophonium (Tensilon) test to exclude myasthenia gravis rarely is performed in infants because safe doses for infants are not established, and borderline-positive test results have been reported in adults with botulism. Barring a hypoxic event, electroencephalographic and neuroimaging study results are normal. Abnormal auditory and visual evoked potentials reflect cranial nerve involvement. Seizures, which occur in 2% to 5% of cases, are rarely unexplained. A patient with raised intraocular pressure has been reported.[62]

Hospital Course

Disease Progression

The natural course of a typical case in a patient with infant botulism is progressive weakness over 2 to 10 days in hospital, remaining at a nadir for 1 to 2 weeks, followed by regaining of abilities slowly.[3,23,39,63,64] Mean duration of hospitalization in California was 3.8 weeks for BoNT/B cases and 5.4 weeks for BoNT/A cases.[63] Manifestations of disease progression are shown in Table 189.3.[23,53,63] Most infants have a progressive inability to swallow or protect the airway that leads to discontinuation of oral feeding, and 75% of these infants require intubation. Some patients require intubation for protection of the airway without the need for mechanical ventilation. Acute respiratory distress syndrome, reported in 5% of patients with botulism in 1 study,[23] was associated with artificial ventilation but otherwise was unexplained.

TABLE 189.3

Associated Events and Complicating Conditions in 111 Hospitalized Infants With Botulism

Percent Occurrence Across Studies		
Associated Events	**Average (%)**	**Range (%)**
Intubation required	77	20–89
Seizures	4	2–5
Acute respiratory distress syndrome	5	—
Failure of oral feeding	89	77–93
Excessive production of antidiuretic hormone	17	16–18
Autonomic instability	11	11
COMPLICATIONS		
Acute otitis media	30	—
Pneumonia	15	7–25
Urinary tract infection	6	0–11
Septicemia	3	0–5

Data from references 23, 53, and 63 (not all findings were reported in all studies).

Seizures are uncommon but are difficult to note clinically in the paralyzed infant; sudden tachycardia is a clue. Seizures are related almost invariably to hypoxia or hyponatremia. The syndrome of excessive secretion of antidiuretic hormone (ADH), reported anecdotally[39] and in 17% in 2 series,[23,53] is almost certainly the result of venous pooling in the paralyzed infant, decreased left atrial filling, and subsequent stimulus to ADH production. Hyponatremia and hypo-osmolality can be profound. Hyponatremic seizure occurred in 1 patient in Philadelphia without the syndrome of inappropriate secretion of ADH as a result of extreme hyponatremia of the mother's milk (a recognized consequence of stress).

Complications

Except for complications directly related to muscular dysfunction, secondary infections are most common in botulism (see Table 189.3), predominantly acute otitis media, aspiration pneumonia, and urinary tract infection. Schechter and associates[65] reported 5 cases of *Clostridium difficile* colitis in infants during or after hospitalization for botulism; toxic megacolon and necrotizing enterocolitis distinguished 2 cases.

Management

The challenges of management are to recognize the diagnosis promptly and before catastrophic events, administer antitoxin urgently, and prevent complications until neuromuscular function recovers. Successful treatment depends on meticulous attention to protect the airway and prevent sudden catastrophic hypoxia, provide adequate ventilation and nutrition, and prevent nosocomial complications. The sensory system is unaffected, and intellectual function is preserved throughout (as documented in adults paralyzed from foodborne botulism).

Antitoxin Therapy

All infants with the suspected clinical diagnosis should be treated urgently with human botulism immune globulin intravenous (BIG-IV/BabyBIG), which neutralizes botulinum toxins. Treatment halts the progression of neuromuscular blockade and should not be delayed for confirmatory testing. This pentavalent antitoxin product is derived from plasmapheresis of donors who received multiple doses of BoNT/A, BoNT/B, BoNT/C, BoNT/D, BoNT/E toxoid vaccine.[66] BabyBIG does not cover the rare occurrence of BoNT/F disease. A 5-year, randomized placebo-controlled (with immune globulin intravenous), blinded clinical trial of the efficacy of BIG-IV was performed in 129 California infants under the sponsorship of the Orphan Drug Program of the FDA and the California Department of Health Services (CDHS).[5] Infants treated with BIG-IV had reductions in duration of hospitalization by 3.1 weeks (from 7.7 weeks to 2.6 weeks), mechanical ventilation by 2.6 weeks, tube or intravenous feedings by 6.4 weeks, and mean hospital charges by $88,600 (in 2004 US dollars).[5] No serious adverse event was attributed to BIG-IV. In the subsequent open-label study of the use of BIG-IV in 366 infants with ultimate laboratory-confirmed botulism who were treated within 7 days of hospitalization, the duration of hospitalization was significantly shorter for those infants treated before 4 days (2.0 weeks) compared with those treated on days 4 to 7 (2.9 weeks).[64] In 2003, BIG-IV was licensed by the FDA to the CDHS as BabyBIG for treatment of infant BoNT/A and BoNT/B cases (and is used with expected effectiveness against BoNT/E). The drug is obtained after consultation with the CDHS Botulism Treatment and Prevention Program (510-231-7600; http://www.infantbotulism.org) and approval of the treating institution's financial officer. The 2015 price was $45,300. BabyBIG, 50 mg/kg body weight, is administered as a single dose intravenously. The mean serum half-life of BabyBIG is 28 days, which is reassuring in light of prolonged intraluminal toxin production in infants. Although the earliest possible treatment is optimal, and only treatment given within 7 days has proven efficacy, BabyBIG usually is given even later to protect against subsequent toxin absorption. Equine heptavalent botulinum antitoxin (BAT) (dosed at approximately 10% of the dose for foodborne botulism) usually is given following confirmation of infant BoNT/F cases,[15] and it has been used occasionally in other BoNT/non-F infant cases outside the US because of cost or expediency.[67] BAT is not without risk and should not be given to infants with botulism if BabyBIG is available. BabyBIG is not licensed, appropriate, or available for use for other forms of botulism. Newer purified recombinant bivalent (rBV A/B) receptor protein antigen vaccine has replaced pentavalent toxoid vaccine in the US,[68] is the current boosting vaccine for BabyBIG donors, and eventually will be the priming vaccine for refresher lots of BabyBIG; BabyBIG then will be effective only for BoNT/A or BoNT/B cases.

Antimicrobial Therapy

Antibiotic therapy is indicated only for the treatment of secondary bacterial infection. Antibiotics with bactericidal activity against *C. botulinum* (e.g., β-lactam agents) do not have an apparent beneficial or detrimental effect on the course of paralysis. Aminoglycoside agents are avoided because they contribute to neuromuscular blockade and have been associated temporally with rapid deterioration in infant botulism. Fever and an abnormal white blood cell count suggest a complicating infection. Ampicillin or amoxicillin is appropriate for treatment of pneumonia, acute otitis media, or sinusitis.

Respiratory Management

Respiratory arrest is the primary cause of death and sequelae, and it can follow days of progressive paresis or occur suddenly, sometimes before the diagnosis or as the diagnosis is suspected. In infants older than 2 months of age, the tempo of progression is apparent over 24 hours, and respiratory failure usually is predictable. In younger infants, obstruction, aspiration, and weakness are concurrent problems requiring preemptive intubation.

The patient is observed under intensive care with continuous monitoring to determine the progression of disease. In general, a history of rapid onset of impairment (over 24 hours rather than days) portends total paralysis and a requirement for ventilation. Nasotracheal or endotracheal intubation is performed when the patient's ability to cough, gag, swallow, or move against gravity (e.g., raising arms or legs while supine) is substantially impaired. Waiting for the appearance of fatigue, apnea, tachypnea, hypercarbia, or hypoxemia is inappropriate.

Positioning with elevation of the planar mattress to 30 degrees at the head allows the flow of saliva by gravity to the posterior hypopharynx, where it is swallowed most easily. Placement of a small blanket roll behind the neck minimizes neck flexion, which can compromise the airway. Optimal positioning with frequent suctioning and the use of nasogastric feeding can avert endotracheal intubation in mildly affected patients. A cloth “bumper” placed below the buttocks prevents sliding and elevates the legs slightly to minimize venous pooling.

Tracheostomy was performed because of prolonged intubation or for fear of postextubation subglottic stenosis in approximately 50% of infants with botulism in 1 institution in Philadelphia before 1981,[53] but not in another institution in the same city,[23] and in <1% of infants reported from California. Immediate or late sequelae of airway trauma are unusual, even when intubation was required for >1 month in the pre-antitoxin era. Tracheostomy should not be performed prophylactically.

Atelectasis and pneumonia can be minimized by careful physiotherapy, suctioning, and positioning and by provision of periodic sighing respirations (even for intubated patients who do not require continuous ventilation). Plugging of the tube and accidental extubation largely are avoidable; experienced personnel must be vigilant and capable of immediate intervention when necessary.

Criteria for extubation are return of gag, cough, and sustained movement against gravity. The mean duration of intubation calculated for all studies before the use of antitoxin was approximately 21 days, with a relatively longer duration for BoNT/A disease. With timely antitoxin treatment, intubation usually occurs for less than 7 days.[5,64]

Nutrition

Enteral feeding is well absorbed and well tolerated because of an apparent relative sparing of paralytic effect on the small bowel. Additionally, enteral feeding stimulates gut motility (which may help purge organisms and toxin), protects the integrity of the enteric mucosa, and obviates the need for an indwelling intravenous catheter. Continuous small-volume nasoenteric (usually nasojejunal) feeding is begun within 48 hours of hospitalization. Caloric needs of the immobile, ventilated infant are approximately two thirds of predicted. A small enema is used judiciously to obtain a stool sample for diagnosis; a therapeutic benefit is not apparent, and vigorous enema or use of a cathartic agent is contraindicated. Human milk or formula is appropriate for feeding.

Oral feedings are resumed when strong swallow, gag, and suck reflexes return, the infant has sustained strength against gravity, and bolus nasogastric feedings have been tolerated.

Weight and fluids and electrolytes are monitored carefully through the nadir of muscular function, to correct initial dehydration and observe for hyponatremia. Intravenous catheters and an indwelling urinary bladder catheter are unnecessary, and their use carries risks of mechanical and infectious complications.

Infection Control

No case of person-to-person transmission of botulism in the home or hospital has been reported. No special isolation of hospitalized infants is recommended. Infants' stools are likely to contain *C. botulinum* organisms and toxin for the duration of hospitalization and beyond. Careful handwashing practices and disposal of diapers as contaminated waste are important. After discharge, circumstances for potential fecal-oral transmission to other young infants (e.g., sharing of cribs) should be avoided for 3 to 4 months.

Outcome and Prevention

Patients who have supportive care before a hypoxic episode have an excellent prognosis, with a <1% mortality rate even before the availability of human BabyBIG. Full recovery without neurologic or neuromuscular sequelae depends on maintaining vigilance and meticulous supportive care while minimizing interventions that increase complications. Peripheral muscular strength and muscles of cranial nerve innervation recover quickly, whereas strength to control the head and trunk recovers slowly (Fig. 189.5), even after BabyBIG.

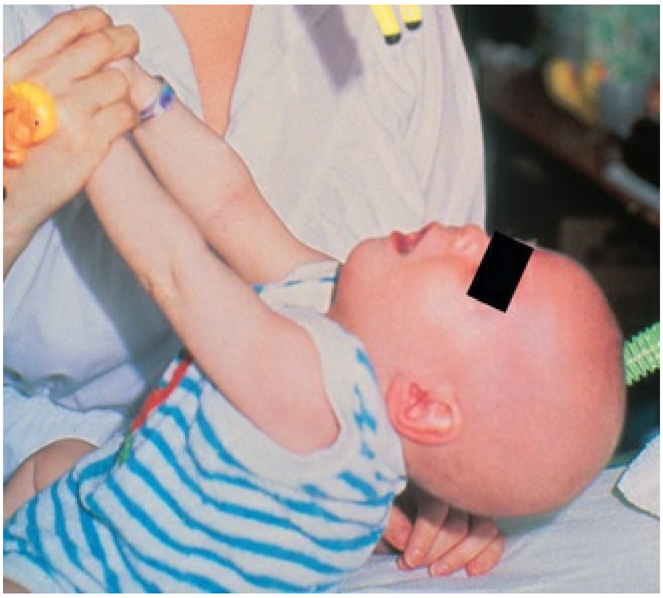

FIGURE 189.5 **Severe head lag in a 4-month-old infant 2 months after infant botulism (1 month after extubation; before the availability of BabyBIG).**

Botulism is uncommon despite unavoidable, frequent environmental exposure to spores. Honey is an avoidable source of spores. The American Academy of Pediatrics and the CDC recommend avoidance of honey for children younger than 12 months of age.[69]

Foodborne Botulism

Foodborne botulism in the US rarely occurs in children. The <10 to 30 cases occurring annually in adults over the past several decades have resulted from improper preparation, preservation, or storage of food (e.g., foiled wrapped or stored in oil) in the home, in restaurants, and in traditional ethnic foods. Most cases are sporadic, and most outbreaks are small, involving 2 or 3 persons. Larger outbreaks, however, occur from commercial and restaurant sources,[70] and in Utah, Arizona and most recently Mississippi in prisons because of consumption of an illicit alcoholic brew (pruno, hooch) (BoNT/A).[71] Toxin types other than BoNT/A and BoNT/B have emerged, especially *C. botulinum* BoNT/E in Arctic regions globally[28,72] and cases caused by *C. baratii* BoNT/F (presumed but not proved to be foodborne).[14,33,34]

Symptoms of descending symmetric paralysis begin 12 to 36 hours (range, 6 hours to 8 days) after consumption of the contaminated food, which usually does not taste tainted. Classic symptoms, including dysphagia, diplopia, dilated and fixed pupils, and dry mouth and throat, occur in an alert patient and are followed by musculoskeletal weakness, postural hypotension, and respiratory paralysis. Ocular symptoms can be heralding manifestations, including blurred near or distant vision (i.e., impairment of accommodation) and diplopia.[73,74] Intoxication caused by BoNT/E has the shortest (1 day) but variable (≤8 days) incubation period and commonly is heralded by nausea and vomiting. Disease caused by BoNT/A is most severe; the rates of required intubation for BoNT/A, BoNT/B, and BoNT/E intoxications are 67%, 52%, and 39%, respectively.[75] Atypical features, such as asymmetric weakness, paresthesia, and sensory abnormalities, have been documented.

Diagnostic methods for foodborne botulism are similar to those for infants, except that toxin assays on serum and potential food source are always performed and results are expected to be positive; results of culture and toxin assay on stool also are positive frequently. Equine antitoxin and supportive care are mainstays of therapy. Antitoxin reduces the mortality rate from BoNT/A intoxication from 46% to 26% and shortens hospital stays.[2,76,77] Since March 2010, BAT—(containing antitoxin to types A, B, C, D, E, F, and G) manufactured with additional steps of purification, immunoglobulin fragmentation, and viral inactivation—has been made under contract by the US Department of Health and Human Services with Cangene Corporation in Canada and is the only product available in the US for noninfant botulism.[77] BAT is available only through the CDC (770-488-7100). Immediate hypersensitivity reaction or serum sickness illness following administration of BAT appears to occur less frequently compared with previous products.[77]

Wound Botulism

Wound botulism was rare in the US in the last half century until the early 1990s in the western US and 2000s in the UK, when a dramatic increase in cases occurred, associated with injection drug users of "black tar heroin" and "skin popping."[4,78] The 12 to 32 cases of wound botulism in the US annually result from *C. botulinum* infection and toxin production in a wound that typically is traumatic and contaminated with soil. Toxin types mirror the soil distribution of spores. When neuroparalytic symptoms and signs begin, the wound itself is clinically unimpressive, with minimal erythema, induration, or serosanguineous discharge and no crepitus or warmth. Gastrointestinal symptoms are less common than in foodborne botulism. Children are affected infrequently, usually after an accidental crush injury and with direct major soil contamination.[79] Facial abscess after laceration from a thrown wood chip was the source of BoNT/A botulism in a 5-year-old child in Washington State.[80]

Diagnostic methods include serum toxin assay and unroofing of lesions to obtain specimens for culture and toxin assay. BAT is given, and the wound is debrided and irrigated vigorously. An anticlostridial agent, such as penicillin or vancomycin, usually is given parenterally, although the benefit is unclear. Wound botulism has occurred despite the use of antibiotic prophylaxis at the time of accidental injury. Debridement of devitalized tissue and vigorous irrigation of wounds are the most effective means of prevention.

Vaccines

The only vaccine existing in the US currently is an rBV A/B vaccine developed at the US Army Medical Research Institute of Infectious Diseases.[68]

Key Points

Infant Botulism

- Age of onset is 2 days through 11 months (median age onset formula fed, 7.6 weeks; human milk fed, 13.7 weeks).
- Beginning of weaning is a period of heightened risk for infants fed human milk exclusively.
- Exposures to *C. botulinum* spores usually are incidental and unavoidable.
- Nearby soil disruption (e.g., construction, dust) or bringing soil into the home (e.g., shoes of construction worker) is common in the history.
- Constipation is a heralding feature.
- Descending symmetric paralysis over hours to days with primary cranial nerve and bulbar involvement and involving the muscles of head control is universal.
- All infants in whom the diagnosis is considered should be monitored under intensive care.
- All infants with suspected cases should be treated urgently with BabyBIG under consultation with the California Department of Health.
- Administration of BabyBIG is associated with an average reduction of hospital stay by 3.1 weeks, mechanical ventilation by 2.6 weeks, and tube feedings by 6.4 weeks.

- Full recovery is expected but slow.

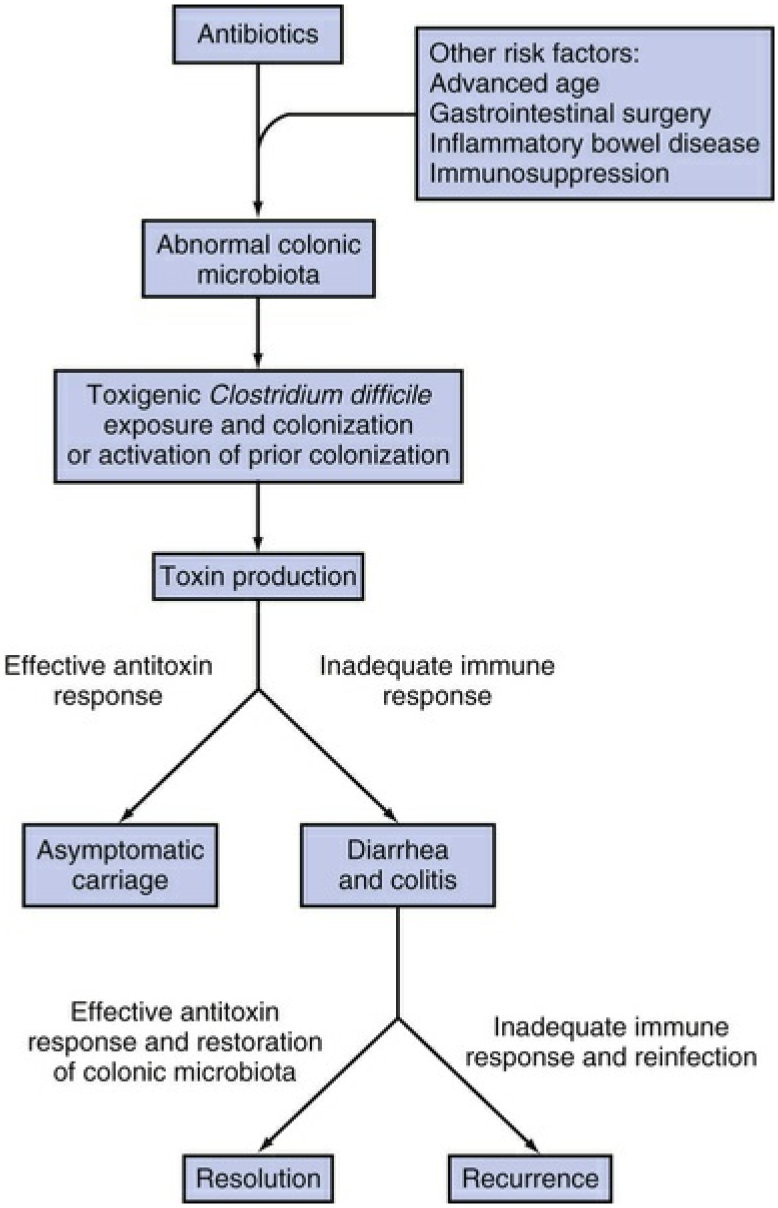
Clostridium difficile

Nalini Singh, Karl Klontz

Description of Pathogen

Clostridium difficile is an anaerobic spore-forming, toxin producing, noninvasive gram-positive bacillus that was first described as part of a study of the intestinal flora of newborn infants.[1,2] *C. difficile* can exist in vegetative or spore forms. Once spores reach the colon, they convert to the functional vegetative form in which the organism becomes susceptible to antimicrobial agents and begins producing exotoxins A (TcdA) and B (TcdB) that cause colitis in susceptible hosts.

Not all colonized patients become symptomatic. For example, colonized young infants can produce antibodies to *C. difficile* without clinical infection, and these antibodies are protective against symptomatic infections later in life.[1] Disturbances in the microbiota of the gut, often as a result of antibiotic use, are believed to permit infection with *C. difficile*[2] (Fig. 190.1). Alteration of the intestinal ecosystem decreases resistance to *C. difficile* colonization.[3] Subsequent ingestion and colonization of *C. difficile* lead to production of exotoxins TcdA and TcbB, which cause intestinal mucosal injury, inflammation, and diarrhea. Animal model studies demonstrated that these toxins disrupt the cytoskeleton and tight junctions of epithelial cells and cause apoptosis.[4,5] TcdB is 10-fold more potent than TcdA in causing human colonic mucosal damage, and certain *C. difficile* strains that produce only TcdB can cause severe disease.[6,7] Various molecular diagnostic tools have been valuable for epidemiologic investigations. For example, a virulent strain of *C. difficile* that emerged in outbreaks in healthcare facilities in the United States and Canada associated with high rates of treatment failure was identified as North American pulsed-field gel electrophoresis type 1 (NAP1), group B1 by restriction endonuclease analysis and as ribotype 027 by polymerase chain reaction testing.[7,8] The epidemic NAP1 strain has upregulated production of TcdA and TcdB compared with other strains, likely secondary to genetic differences in regulatory genes.[8,9] This *C. difficile* strain has a high level of resistance to fluoroquinolones. The hypervirulent NAP1 strain of *C. difficile* has been reported in a small proportion (20%) of affected children.[10]



Antibiotics
Other risk factors:
Advanced age
Gastrointestinal surgery
Inflammatory bowel disease
Immunosuppression
Abnormal colonic microbiota
Toxigenic *Clostridium difficile* exposure and colonization or activation of prior colonization
Toxin production
Effective antitoxin response
Inadequate immune response
Asymptomatic carriage
Diarrhea and colitis
Effective antitoxin response and restoration of colonic microbiota
Inadequate immune response and reinfection
Resolution
Recurrence

FIGURE 190.1 **Pathogenesis of *Clostridium difficile* infection.** (From Leffler

DA, Lamont JT. *Clostridium difficile* Infection. N Engl J Med 2015;372:1539–1548.)

Epidemiology

In the past decade, *C. difficile* infection in children has extended from healthcare to community settings.[11,12] *C. difficile* spores are present in asymptomatic neonates, healthy young infants, soil, and healthcare and childcare environments. *C. difficile* spores are resistant to heat, acidic environments, antibiotics, and most antiseptics, and this resistance allows the organisms to survive in the environment for prolonged periods.[13] *C. difficile* can be acquired from infected or colonized people and from contaminated environments or equipment. Neonates can become colonized without developing symptomatic illness. In a study involving active population- and laboratory-based surveillance across 10 geographic areas in the US, the Centers for Disease Control and Prevention (CDC) reported that, in 2011, the estimated number of incident *C. difficile*–associated diarrhea (CDAD) infections in the US was 453,000, and the estimated number of deaths caused by *C. difficile* infection was 29,300; overall, 35% of cases were community associated.[14] In the same study, the lowest incidence of infection was seen in children 1 to 17 years of age (24.2 cases per 100,000 population); in this age group, the incidence of community-associated and healthcare-associated CDAD was 17.9 and 6.3 per 100,000 persons, respectively.[14]

Molecular diagnostic tools such as nucleic acid amplification tests have helped define the incidence of CDAD further.[15,16] CDAD in adults has become the most common cause of healthcare-associated infection in the US, with excess healthcare costs estimated to be $4.8 billion annually.[17,18] Among children evaluated for diarrhea in a children's hospital emergency department in Seattle, Washington, *C. difficile* was the third most common cause, trailing viral and other bacterial causes.[19] Similarly, in the Washington, DC area in 2004 to 2005, increased numbers of community-acquired CDAD infections were documented in children with few previous antibiotic exposures.[11]

Some US states and Canadian provinces require hospitals to report incidence rates of CDAD.[20,21] Risk factors associated with

CDAD include exposure to antimicrobial therapy, use of antineoplastic agents, repeated enemas or use of gastrointestinal stimulants, underlying bowel disease (e.g., inflammatory bowel disease or Hirschsprung disease), gastrointestinal surgical procedures, and renal insufficiency.[22–27] CDAD has been associated with almost every antibiotic, but it is associated more frequently with penicillins, macrolides, clindamycin, cephalosporins, and fluoroquinolones.[28]

Clinical Manifestations

The spectrum of clinical manifestations associated with *C. difficile* infection ranges from asymptomatic colonization with toxigenic strains to pseudomembranous colitis and toxic megacolon. Asymptomatic colonization and toxin production are common in infants, with up to 50% of children <1 year of age being carriers. The most common clinical presentation of CDAD is mild to moderate diarrhea; some patients have mucus or blood in stool. Children with pseudomembranous colitis can have diarrhea, fever, abdominal distention, cramps, pain, and systemic toxicity such as malaise, anorexia, and dehydration. Occasionally, some children develop severe disease associated with complications such as toxic megacolon. Other complications such as sepsis, ascites, intestinal perforation, intussusception, pneumatosis, and rectal prolapse are reported rarely.[29,30] Severe cases of CDAD occur most frequently in neutropenic children with leukemia and in patients with inflammatory bowel disease. Extraintestinal manifestations of *C. difficile* are extremely rare, but cases of bacteremia, osteomyelitis, reactive arthritis, and splenic abscesses are reported.[31–34] Disease characteristically begins while the child is hospitalized and receiving antimicrobial therapy, but it can occur weeks after hospital discharge. Coinfection with enteric viruses (e.g., rotavirus or calicivirus, or both) has been reported in patients with severe cases of CDAD requiring intensive care.[35]

Laboratory Findings and Diagnosis

Detection of *C. difficile* toxins in stool specimens provides the most practical and clinically relevant method for diagnosis of *C. difficile*–associated diseases. *C. difficile* testing should be performed only on diarrheal stool samples, usually from children who have received antibiotics within the previous 2 months or in whom diarrhea began 72 hours after hospitalization and especially in patients with other risk factors. Testing also is appropriate for children with community-associated colitis whose cultures do not reveal other bacterial pathogens. Enzyme immunoassay kits can detect TcdA and TcdB, but have relatively low sensitivity (63%–94%), with higher specificity (75%–100%).[28,38] In the preferred 2-step method, enzyme immunoassay first is used to detect *C. difficile* glutamate dehydrogenase, an enzyme constitutively produced by toxigenic and nontoxigenic *C. difficile*.[39–41] Stools with a positive rapid screen result then are tested for toxin.[41,42] Nucleic acid amplification tests combine good sensitivity and specificity and are rapid stand-alone tests. Positive predictive value, especially in children <5 years of age, remains to be determined.[42]

Direct visualization of mucosal plaques or pseudomembranes on colonic mucosa by endoscopy is required to establish the diagnosis of pseudomembranous colitis. Because of the cost and risk associated with the procedure, endoscopy should be reserved for patients in whom other disease processes are being considered or for severely ill patients in whom a strong clinical suspicion for *C. difficile* infection exists despite negative results of noninvasive tests such as a toxin assay.[43]

Differential Diagnosis

Viral gastroenteritis caused by agents such as rotavirus, adenovirus, and enterovirus can have manifestations similar to those of mild *C. difficile* infections. For moderate to severe CDAD, bacterial causes such as *Salmonella, Shigella, Yersinia, Campylobacter,* or toxigenic *E. coli* should be considered because these infections can cause local and systemic inflammation. Parasitic infections such as with *Giardia* or *Cryptosporidium* also should be considered, especially if the course of diarrhea is protracted and stools are not bloody. Noninfectious causes such as inflammatory bowel disease also can mimic *C. difficile* infections. Appendicitis, typhlitis, intussusception, necrotizing enterocolitis, neutropenia-associated colitis, or other acute intra-abdominal diseases should be considered in extremely ill patients.

Treatment

Treatment for initial episodes of *C. difficile* infection consists of discontinuation of the precipitating antimicrobial agent or agents and initiation of metronidazole (oral or intravenous) or vancomycin (oral only) therapy.[28] The efficacy of these antimicrobial regimens for *C. difficile* infection has been demonstrated in randomized studies, mostly involving adult patients.[44,45] Oral metronidazole (30 mg/kg/day in 4 divided doses, maximum 2 g/day) is the drug of choice for initial treatment of mild to moderate *C. difficile* infections. Oral vancomycin (40 mg/kg/day in 4 divided doses, maximum of 2 g/day) is indicated in patients with severe disease (e.g., hospitalized in an intensive care unit), patients with underlying intestinal disease, or patients who are unresponsive to metronidazole therapy; efficacy is modestly superior to that of metronidazole.[46,47] Vancomycin is not effective if given intravenously. For patients with severe disease and complications such as shock, ileus, or toxic megacolon, addition of intravenous metronidazole to vancomycin orally or by enema is recommended. The duration of therapy for any regimen should be a minimum of 10 days; most patients demonstrate clinical improvement within 24 to 48 hours of initiation of therapy and resolution of diarrhea within 4 to 5 days. Toxin testing as a routine follow-up study is not recommended.

In addition to antimicrobial therapy, supportive care with fluid, electrolyte, and nutrition replacement should be provided. Antimotility drugs should not be administered to patients with *C. difficile* infections because of the associated risk of developing ileus or toxic megacolon.[48] Surgical intervention, such as colectomy, can be lifesaving in selected patients with complications such as intestinal perforation or toxic megacolon.[49]

Relapses of *C. difficile* infection are observed in up to 25% of patients after initial therapy is discontinued. The first relapse episode is treated with the same regimen as the initial episode. For second or later relapses, an oral vancomycin regimen tapered over weeks, or pulse therapy of repeated interspersed 1 week of therapy followed by 1 week without therapy, is preferred based on studies involving adults.[50] Use of metronidazole beyond the first relapse episode should be avoided because of the potential for cumulative neurotoxicity.[47] Use of fidaxomicin, a poorly absorbed, bactericidal antibiotic, has been approved for use in adults with CDAD, is noninferior to oral vancomycin for treatment, and appeared to reduce the risk of recurrence to 15% versus 25% for patients receiving oral vancomycin.[51,52] Nitazoxanide also is an effective therapy in adults. Adults with multiple relapses have been treated with fecal transplantation to restore gut microbiota.[53–55] Studies evaluating the efficacy of the probiotic *Saccharomyces boulardii* in preventing relapses have been inconclusive[56]; caution must be taken because *S. boulardii* has been associated with bloodstream invasion in immunocompromised patients and in patients with a central venous catheter.[57] In 1958 Eiseman et al. reported the use of fecal enema as an adjunct in the treatment of pseudomembranous enterocolitis.[58] Since that report, multiple studies have demonstrated fecal microbiata transplantation (FMT) to be more effective for the treatment of recurrent *C. dificile* infections in adults than antibiotics, with resolution of symptoms without recurrence varying from 77% to 100%, depending on route of administration.[59] Based on small case series in the absence of randomized clinical trials, similar rates of success have been reported for FMT in the setting of pediatric recurrent *C. dificile* infections.[60]

Prevention

Meticulous hand hygiene with soap and water should be performed before and after donning gloves when any contact is expected with patients infected with *C. difficile*. All healthcare personnel should use glove and gown precautions when in contact with the patient *and* the surrounding environment.[61,62] Waterless gel is ineffective in killing spores of *C. difficile*. Cases of healthcare-associated CDAD in healthcare personnel have occurred. Children with CDAD should not attend out-of-home childcare facilities while symptomatic with diarrhea.

Environmental contamination plays an important role in the transmission of *C. difficile*.[28] *C. difficile* has been transmitted through electronic thermometers.[63] Endoscopes have not been implicated in *C. difficile* transmission. The degree to which the environment becomes contaminated is proportionate to the patient's severity of disease. Diluted sodium hypochlorite successfully eradicates spores, whereas routine hospital cleaning agents such as quaternary ammonium compounds are ineffective. Vaporized hydrogen peroxide delivered through a special apparatus is successful in reducing environmental contamination of *C. difficile*.[64] This procedure can be carried out in vacant hospital rooms and requires that the room be sealed off to ensure efficacy and avoid inadvertent exposure to patients. The effectiveness of this technology needs further evaluation. Comprehensive strategies to prevent *C. difficile* that include antimicrobial stewardship have been published.[65] A promising first-in-human phase 1 vaccine trial in adults using toxoid antigens was published in 2016.[66]

Key Points

Diagnosis and Management of *Clostridium difficile* Infection

Epidemiology

- Acquired from infected people or contaminated environments, especially healthcare environments
- Evolving from healthcare-associated to community-acquired infection
- Exposure to antibiotic therapy a risk factor for developing disease
- Neonates can be colonized without symptomatic illness.

Clinical Features

- Most commonly manifesting as mild to moderate diarrhea with or without mucus or blood in stool
- Pseudomembranous colitis
- Complications including toxic megacolon, intestinal perforation, sepsis, ascites, intussusception, and pneumatosis intestinalis

Diagnosis

- Detection of C. *difficile* toxins
  - Two-step enzyme immunoassay first to detect glutamate dehydrogenase (sensitive but nonspecific) and then to detect toxin if step 1 is positive
  - Stand-alone nucleic acid amplification test

Treatment

- Discontinuation of precipitating antibiotic
- Initial infection:
  - Mild to moderate disease: oral metronidazole 30 mg/kg/day in 4 divided doses, maximum 2 g/day
  - Severe disease, as in patients who are in an intensive care unit, have proven pseudomembranous colitis, have underlying intestinal disease, or are unresponsive to metronidazole therapy: oral vancomycin 40 mg/kg/day in 4 divided doses, maximum 2 g/day
  - Severe disease with shock, ileus, or megacolon: vancomycin enema and intravenous metronidazole
  - Duration of therapy a minimum of 10 days
- Relapse infection:
  - First relapse: same regimen as the initial episode

- Second or later relapse: oral vancomycin in therapeutic and then tapered or pulsed therapy are recommended. Metronidazole should not be used for treatment of a second recurrence because neurotoxicity is possible.
- Fidaxomicin approved for treatment in adults

Other *Clostridium* Species

Itzhak Brook

Clostridia are gram-positive, spore-forming bacilli that cause up to 10% of anaerobic infections[1–5] and occur at diverse clinical sites. Of the more than 200 recognized species of *Clostridium*, <20 are associated with invasive and toxigenic human diseases. Clostridial species vary in oxygen tolerance, nutritional needs, motility, and optimal temperature for growth. They can cause distinct clostridial histotoxic syndromes by means of specific clostridial toxins (e.g., gas gangrene, food poisoning) and other, nonsyndromic clostridial infections (e.g., bloodstream infection [BSI]). Clostridia also are recovered from various sites as part of polymicrobial infections,[4,5] including intra-abdominal, biliary tract, female genital tract, pleuropulmonary, central nervous system, and skin and soft tissue infections.[3]

Clostridia are members of the normal human flora, present primarily in the intestinal tract and vagina.[4] They colonize the gut of other vertebrates and insects and are ubiquitous in soil. Clostridia are part of the phylum Firmicutes and based on 16S (small subunit) ribosomal DNA sequence analysis can be divided into 11 homology groups. Most of the clinically significant species are part of group 1.[6] Most clostridial infections in children are polymicrobial and arise from the site of endogenous colonization; the organisms gain access when normal mucocutaneous barriers are disrupted as from surgical procedures, trauma, a perforated viscus, necrotizing enterocolitis, or chemotherapy-related mucositis.[3] Devitalized tissue and low oxidation reduction potential enhance the growth of clostridia. Contamination of existing wounds or surgical sites with organisms from soil, unsanitary water, contaminated objects, and human and animal feces can lead to infection.

Clostridial species that cause gas gangrene produce extracellular toxins or possess virulence factors such as enzymes or lysis factors. Clostridia that cause gastrointestinal disease produce enterotoxins.[7]

Clostridium perfringens is the most common clinical isolate of the genus. It is a ubiquitous bacterium associated with several exotoxin-mediated clinical diseases. *C. perfringens* has 12 recognized toxins, and the species is divided into types A through E on the basis of toxins produced.[7] *C. perfringens* causes food poisoning,[8] necrotizing enteritis,[9] and gas gangrene.

Clinical Manifestations

Histotoxic Infections

Table 191.1 shows characteristics of histotoxic infections and the likely responsible *Clostridium* spp. *C. perfringens* is the most common pathogen associated with gas gangrene.[10] Other responsible organisms that can also produce exotoxins are *C. bifermentans, C. sordellii, C. septicum, C. novyi,* and *C. histolyticum.* The spectrum of infection includes cellulitis, necrotizing fasciitis, and severe myonecrosis (gas gangrene).[11] Severe myonecrosis often is a polymicrobial infection that occurs after bacteremic spread from an intestinal site of colonization to traumatized soft tissue.

TABLE 191.1

Clinical Manifestations of Histotoxic Clostridial Infection

Disease	Comment
Localized skin or soft tissue infection	Polymicrobial; related to trauma or ischemia; frequently remains localized but with extensive necrosis; perirectal abscess, decubitus ulcers
Spreading cellulitis or fasciitis	*Clostridium ramosum, Clostridium perfringens, Clostridium septicum* usual pathogens; compartment syndromes; 50% mortality rate
Myonecrosis	*C. perfringens, C. sordellii* responsible for >75%; related to trauma or ischemia;

(gas gangrene)	extremities or abdominal wall; aggressive surgical debridement required; usually fatal
Disseminated myonecrosis	*C. septicum, C. sordellii,* or *C. perfringens* usually responsible; no predisposing trauma; highly associated with profound neutropenia, colorectal or hematologic malignant disease, intestinal insult; spreading cellulitis and crepitation; survival rare
Suppurative visceral infection	Polymicrobic, with *C. perfringens, C. ramosum* especially; associated with cholangitis, pancreatic disease, pelvic infections, intra-abdominal abscess, pulmonary aspiration
Bacteremia or septicemia	*C. perfringens* associated sometimes with relatively benign course; *C. septicum* and *C. sordellii* rapidly progressive, causing disseminated gas gangrene

In adults, the predisposing factor for BSI often is colorectal or hematologic malignant disease, inflammatory bowel disease, or hemodialysis.[12,13] Trauma to the colon or female genital tract or injection drug abuse is present in most patients with BSIs. *C. sordellii* and *C. septicum* deserve special note because of the generally rapidly fatal course of infection. *C. septicum* septicemia in children usually is associated with profound neutropenia (as a primary genetic disorder or related to malignant disease or chemotherapy).[14] Typhlitis, mucositis, or necrotizing enterocolitis frequently is present, but some cases occur spontaneously.[15] In such cases, BSI and generalized soft tissue infection progress rapidly, and gas production is evident clinically at widely distributed body sites (Fig. 191.1).[16] Survival is unusual. *C. septicum* septicemia and secondary brain abscess can complicate hemolytic uremic syndrome caused by *Escherichia coli* O157:H7,[17,18] bowel ischemia, or trauma, and the combination often is fatal.[19] *C. sordellii* infections occur in previously healthy people following induced or spontaneous abortion, childbirth, genital tract operations, skin or soft tissue trauma, or injection drug abuse.[20] Lethal and hemorrhage toxins are thought to be responsible for typical leukemoid reactions and high fatality rates.[21] Clostridial endocarditis is rare. Clostridial bacteremia can be transient, without clinical consequence, or it can represent a contamination. In infants, BSI can be associated with necrotizing enterocolitis.[22]

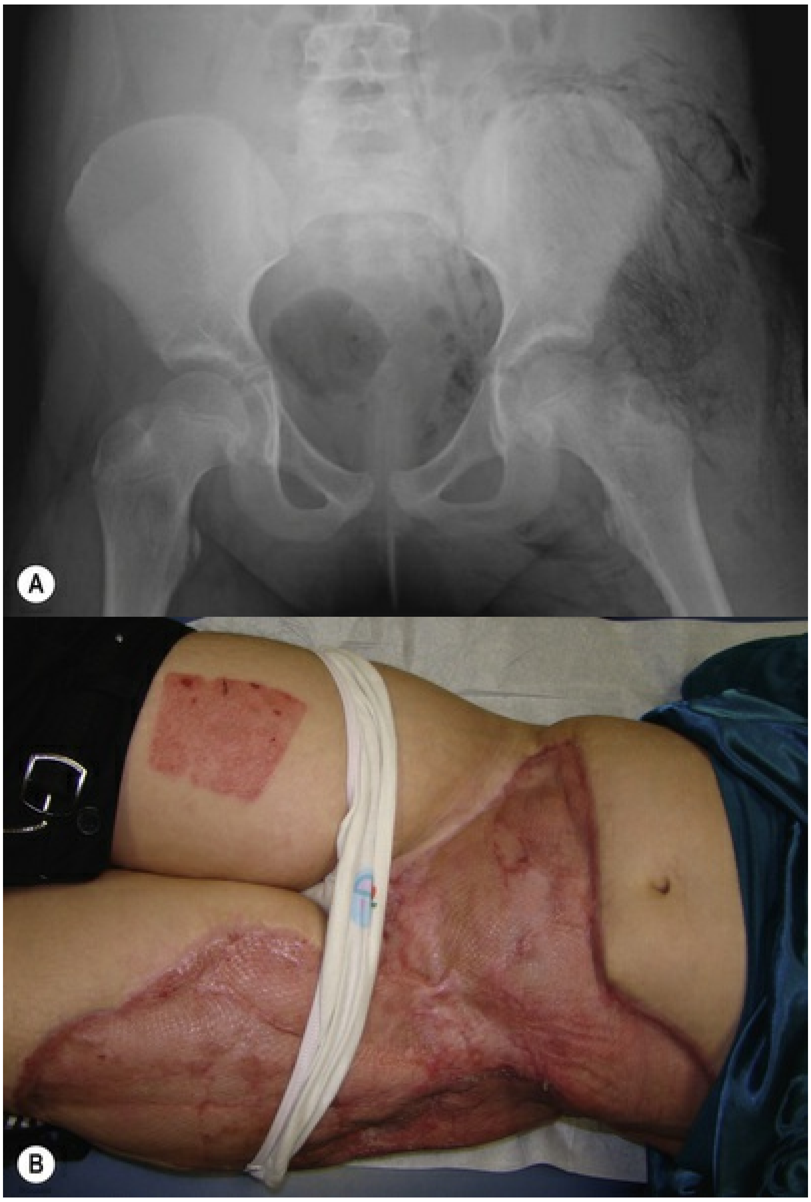

FIGURE 191.1 A 9-year-old girl with MyD88 deficiency (caused by myeloid differentiation primary response gene) had a 5-day history of abdominal pain and acute onset of left thigh and buttock pain. (A) Frontal radiograph shows diffuse, left-sided linear radiolucencies indicative of gas in muscle planes and soft tissues. (B) Urgent, widely extensive, and frequent operative debridement procedures were performed, followed by muscle flap and grafting. *Clostridium septicum* was isolated from tissue. (Courtesy of D. Conway, W. Davis, and S. S. Long, St. Christopher's Hospital for Children, Philadelphia, Pa.)

Gas gangrene affects muscle tissue that has been compromised by surgical procedures, trauma, or vascular insufficiency and that is contaminated with *C. perfringens* spores, usually from foreign material, such as clothing, dirt, or a medical device.[23] The ubiquitous nature of *C. perfringens* spores in dirt, soil, and clothing and on skin, especially of the lower trunk, provides multiple opportunities for inoculation of wounds.[24] The metabolic requirements of *C. perfringens* for growth are the major factors in the establishment of clostridial myonecrosis.

After inoculation and outgrowth of C*. perfringens* in the muscle, severe, rapidly progressive myonecrosis results from toxins elaborated, principally the α-toxin.[7] The α-toxin is a lecithinase that rapidly lyses cell membranes and causes hemolysis, myofibrillar injury, and vascular permeability. Severe systemic manifestations accompany local infection and may be toxin related. The patient has fever, tachycardia, and diaphoresis and is alert, anxious, and apprehensive or apathetic. Shock and attendant multiorgan failure ensue in most cases.

Gas gangrene characteristically begins 1 to 4 days (range, 6 hours to 21 days) after an injury.[24] The onset is heralded by sudden and persistent pain at the site of injury and an accompanying limb "heaviness." Overlying skin appears normal at the onset but quickly becomes cool, pale, and waxy as a result of ischemia. Local tense swelling, tenderness, pallor, and a thin hemorrhagic exudate are noted first; pallor gives way to a bronze or magenta discoloration, and hemorrhagic (purplish) bullae appear. Pain remains the most prominent symptom. Soft tissue crepitation can be present, but if the amount of gas is small, this finding may be noted first on a plain radiograph or other imaging study. As the condition worsens, a peculiar offensive odor (sometimes described as sweet) is noted, and a brown serosanguineous discharge is present. Gram stain of discharge shows large numbers of gram-positive bacilli with few or no white blood cells. Involved muscle can be edematous and pale initially, advancing to a mottled appearance and greenish black gangrene. Consistency of the muscle changes from pasty and mucoid to friable and liquefied.

Tachycardia, widespread myalgia, anxiety, and diaphoresis despite low-grade fever appear early and progress rapidly to hypotension, poor perfusion, disseminated intravascular coagulation, and mental status changes.[23,24] Without definitive therapy, the disease progresses inexorably, with high fever (often with rigors), shock, renal failure, metabolic acidosis, and coma, to death. Clostridial septicemia can occur terminally.

Food Poisoning

Acute self-limiting gastroenteritis caused by contaminated food products (mostly meat products) often is associated with *C. perfringens* and its toxins.[8] *C. perfringens* has been documented as the third most common cause of outbreaks of foodborne disease (after *Salmonella* and *Staphylococcus aureus*). Food poisoning occurs as a result of ingestion of vegetative forms of *C. perfringens* that develop in foods standing at a temperature between 30°C and 50°C.[25] Primary contamination of meat with *C. perfringens* spores is common. The temperature of cooking meat must exceed 120°C to ensure that spores are killed. With cooking at lower temperatures, spores can be converted to vegetative forms during cooling of food, thus risking the growth of *C. perfringens* in the gastrointestinal tract.

Although the symptoms of *C. perfringens* food poisoning are attributable largely to the action of enterotoxins, these enterotoxins usually are formed in the gut after ingestion of the organisms. Ingestion of preformed toxin results only in diarrhea if gastric acidity has been neutralized. The enterotoxin formed in vivo is a 35-kd polypeptide that is heat and acid labile and is inactivated by some proteolytic enzymes.[7] The enterotoxin gene *cpe* can be used to detect illness-causing strains. The toxin inhibits absorption of glucose and secretion of water, sodium, and chloride, and it strips the epithelium of villous tips. The in vitro cytotoxic effect is similar to that of *Shigella* toxin but differs from that of cholera or *E. coli* enterotoxins. Adenyl cyclase appears not to be involved in the mediation of *C. perfringens* toxin activity. The resultant gastroenteritis has components of secretory and inflammatory diarrhea.

C. perfringens food poisoning is an acute, self-limiting diarrheal illness with an onset 6 to 24 hours after consumption of contaminated food.[25] Crampy abdominal pain commonly accompanies watery diarrhea, which does not contain blood or mucus. Fever, nausea, and vomiting occur rarely. The duration of disease is commonly <24 hours, and medical intervention usually is not warranted or sought, except in the case of outbreaks. Making the distinction between food poisoning caused by *C. perfringens* and that caused by *Bacillus cereus* is difficult.

Differentiating this acute diarrheal disease from the numerous other viral, bacterial, and toxic causes of diarrhea on clinical grounds can be difficult unless an outbreak has occurred.[26] The absence of fever, nausea, vomiting, and blood or mucus in stools in a patient with *C. perfringens* diarrhea makes *Salmonella, Shigella, Campylobacter, Yersinia,* and rotavirus infection unlikely. The duration of infection caused by these pathogens usually is more prolonged than *C. perfringens* food poisoning. The diagnosis can be confirmed only by isolation of large quantities of *C. perfringens* from the suspect food ($>10^6$ colony-forming units/g) and the patient's fecal samples. The enterotoxin can be detected using a cytopathic toxin neutralization assay, latex agglutination, or enzyme immunoassays.[27] However, this approach is not useful in clinical diagnosis.

Miscellaneous Infections

Clostridia can contribute to various polymicrobial infections in children, including arthritis, osteomyelitis, skin and soft tissue (often after trauma or foreign body penetration), intra-abdominal, pulmonary, intracranial, and pelvic infections and abscesses.[5] Clostridial septicemia is rare in children without malignant disease, aplastic anemia, or immunodeficiency and usually follows an ischemic gastrointestinal insult, such as with neonatal necrotizing enterocolitis or toxic megacolon.[5] Pneumatosis cystoides intestinalis is present and extensive. Highly lethal enteritis necroticans, uncommon in the United States, is associated with consumption of undercooked pork (pigbel); *C. perfringens* with type C enterotoxin is usually the cause.[28] Neutropenic enterocolitis (typhlitis) is seen in patients with congenital neutropenia, leukemia, or neutropenia resulting from cytotoxic chemotherapy and usually is associated with *C. septicum*, but other clostridia have been implicated.[29] *Clostridium* spp. of normal flora (especially *C. perfringens* and *C. ramosum*) also are associated with septic abortion and puerperal septicemia, and mortality rates are high.[30] *C. perfringens* has been reported to cause panophthalmitis in children.[31]

Diagnosis

Gas gangrene is a clinical diagnosis. Myonecrosis and crepitation are classic findings but are not pathognomonic because several facultative and anaerobic bacteria produce gas. Synergistic nonclostridial anaerobic myonecrosis can have local clinical manifestations similar to those of gas gangrene but usually with less severe systemic symptoms. Localized anaerobic cellulitis is more likely to have gradual onset and less pain or systemic toxicity and is difficult to distinguish locally from group A streptococcal infection associated with exotoxin A–producing strains. A preexisting wound in streptococcal disease, however, usually is minor, whereas in anaerobic cellulitis and myonecrosis, severe crush injury is the expected predisposing injury[3,23]

Gram stain of local lesions reveals gram-positive bacilli, usually in the absence of neutrophils. Isolation of *C. perfringens* from a wound is not diagnostic of gas gangrene, and an inability to isolate *C. perfringens* does not exclude the diagnosis.[32,33] Isolation from a deep tissue site should be attempted (see Chapter 187).

Treatment

Histotoxic Infections

Early and aggressive surgical debridement of affected tissues is critical to successful outcome. Urgent intervention may require radical debridement to decompress fascial compartments and prevent further tissue anoxia and to provide drainage. Amputation of extremities may be required. Commonly, several surgical procedures must be performed to remove all necrotic tissue and any compromised tissue as it becomes necrotic.

Specific antimicrobial therapy directed at *Clostridium* spp. should be administered while recognizing that the anoxic and acidic environment of dead muscle is not conducive to antimicrobial efficacy. Penicillin G has excellent activity against most *Clostridium* spp. and always should be included in regimens for treatment of rapidly spreading clostridial cellulitis, myonecrosis, or septicemia. However, increasing resistance of *Clostridium* spp. to penicillin has been noted.[34] Clindamycin, cefoxitin, and metronidazole are clinically inferior, and some *Clostridium* spp. (especially *C. ramosum, C. tertium, C. sporogenes*) are resistant. The drug of choice is penicillin G, in a dose of 200,000 to 400,000 U/kg/day given intravenously in divided doses every 4 hours. Clindamycin has an advantage over penicillin because it suppresses bacterial toxin synthesis. The combination of penicillin and clindamycin was found to be more effective than penicillin alone in a mouse model.[35] Other effective antimicrobial agents are chloramphenicol, later-generation cephalosporins, the carbapenems, and vancomycin. Treatment should be continued until BSI has cleared and symptoms have resolved.

Aggressive supportive care is essential and predictably is complex. Although no controlled data are available and pediatric studies are lacking, hyperbaric oxygen appears to be useful in treating gas gangrene.[36] However, if fasciotomy is indicated, the procedure should not be delayed for hyperbaric oxygen therapy, nor should aggressive support be forfeited. The major advantages of hyperbaric oxygen may be in minimizing tissue loss and diminishing the extent of debridement required. Complications, including oxygen toxicity, mental status changes, and tympanic membrane perforation, are significant; survival may not exceed that obtained by an aggressive surgical approach. The use of polyvalent antitoxin (of equine origin) has been advocated, but substantive supportive data are not available. Other adjuvant therapies include granulocyte colony-stimulating factor, granulocyte transfusions, and immunoglobulin intravenous.[19]

The prognosis for survival depends on the location and extent of disease and the promptness of appropriate debridement. Death is virtually certain if surgical treatment is delayed (e.g., in a wartime situation). The overall survival rate, however, approaches 75% to 90% with early, modern, aggressive treatment.

Food Poisoning

Because of the self-limiting nature of *C. perfringens* food poisoning, medical intervention rarely is warranted. Oral rehydration with hypotonic fluids generally suffices, although in unusual circumstances, particularly in infants, intravenous hydration may be required. Antibiotics serve no useful purpose in this disease and should not be used; no antitoxin is available.

Prevention

Histotoxic Infections

The keys to prevention of histotoxic infections are adequate cleaning and debridement of contaminated wounds. Antimicrobial treatment, best considered therapeutic rather than prophylactic in this setting, should be administered to patients with heavily contaminated wounds, and care should be taken to avoid the anaerobic environments created by closing the wounds. Meticulous attention to the principles of surgical wound management prevents most cases of surgical wound gas gangrene.

Food Poisoning

The best means of preventing food poisoning from *C. perfringens* is appropriate handling of cooked foods (especially meats). Meats should reach at least 120°C during cooking and, if not consumed while hot, should be stored at <5°C.[37] Meat allowed to stand at room temperature is permissive to growth of *C. perfringens.* Preformed toxin is destroyed with reheating to serving temperature, although this temperature does not affect spores. Inhomogeneous heating, as can occur in microwave ovens, can leave some toxin undestroyed and should be avoided.

Bacteroides and *Prevotella* Species and Other Anaerobic Gram-Negative Bacilli

Itzhak Brook

Clinically important anaerobic gram-negative bacilli (AGNB) include *Bacteroides, Prevotella, Porphyromonas,* and *Fusobacterium. Fusobacterium* is discussed in Chapter 193. Infection with *Porphyromonas* and *Prevotella* (previously mainly *Bacteroides* species) is not common in children, except for *Prevotella melaninogenica* and *Prevotella intermedia.*[1,2] Changing taxonomy has caused considerable clinical confusion in recategorization of *Bacteroides* species. Additionally, many new genera and several new species have been created to accommodate pathogens such as *Bilophila wadsworthia, Sutterella wadsworthensis, Centipeda periodontii,* and *Anaerobiospirillum thomasii* (see Chapter 187).

Bacteroides and *Prevotella* are gram-negative, obligate anaerobic bacteria that constitute a major part of the normal flora of the mouth, gastrointestinal tract, and female genital tract.[3] The

Bacteroides fragilis group comprises the species of Bacteroidaceae that occur with greatest frequency in clinical infections. These organisms are resistant to penicillins mostly through the production of β-lactamase.[4] The group includes *B. fragilis* (the most commonly recovered member), *B. ovatus, B. thetaiotaomicron,* and *B. vulgatus.*[5] *B. distasonis* is classified now as *Parabacteroides distasonis.*[6] *Bacteroides* spp. reside primarily in the large intestine and predominate in infections that originate from gut flora (e.g., perirectal abscesses following perforation or surgical procedures, intra-abdominal abscesses, decubitus ulcers). A heterogeneous group of *Bacteroides* spp. *(B. ureolyticus, B. gracilis, B. forsythus)* have a less clear taxonomic relationship and may be more closely related genetically to *Campylobacter.* Pigmented *Prevotella,* previously called the *Bacteroides melaninogenicus* group *(P. melaninogenica* and *P. intermedia),* and *Porphyromonas (Porphyromonas asaccharolytica)* and nonpigmented *Prevotella (P. oralis, P. oris)* are part of the normal oral and vaginal flora and are the predominant gram-negative anaerobic species isolated from contiguous oral respiratory tract infections, such as aspiration pneumonia, lung abscess, chronic otitis media, chronic sinusitis, abscesses around the oral cavity, human bites, paronychia, brain abscesses, and osteomyelitis. *Prevotella bivia* and *P. disiens* (previously also called *Bacteroides*) are important in obstetric and gynecologic infections.

Bacteroides spp. possess virulence factors or special characteristics to compete successfully for microbial niches, including pili and fimbriae (which enhance adherence),[1,7] hemagglutination, enzymes (collagenase, phospholipase A, hemolysin, peroxidase, protease, fibrolysin, heparinase, neuraminase, superoxide dismutase),[8,9] and lipopolysaccharide and capsular polysaccharide (which enhance invasion and evasion from host phagocytosis). *B. fragilis* and *P. melaninogenica* are associated more frequently with infection than their relative density in normal flora would predict, and they are especially associated with abscess formation (see Chapter 187).

Pathophysiology

Most infections with AGNB originate from the endogenous mucosal flora. This feature allows for logical selection of antimicrobial agents for the treatment of infections predictably caused by anaerobic bacteria. AGNB infections generally are polymicrobial, and the number of unique isolates can reach 5 to 10. The types of other copathogens depend on the site and circumstances of the infection. AGNB promote infection through synergy with their aerobic and anaerobic counterparts. An indirect pathogenic role of AGNB is conferred by the ability of these organisms to produce a β-lactamase enzyme. Such organisms may protect not only themselves but also other penicillin-susceptible organisms from the activity of penicillins.[10]

Clinical Manifestation and Prediction of Pathogens

Central Nervous System Infections

Anaerobic bacteria, including AGNB, can cause a variety of intracranial infections: brain abscess, subdural empyema, epidural abscess, and meningitis.[11,12] Infection generally is polymicrobial, mixed with microaerophilic streptococci. The main source of brain abscess is an adjacent, generally chronic infection in the middle ear, mastoid, sinus, oropharynx, teeth, or lungs. Middle ear or mastoid infections tend to spread to the temporal lobe or cerebellum, whereas sinusitis often causes abscess of the frontal lobe. Hematogenous spread often occurs after dental, oropharyngeal, or pulmonary infection.[13,14] Rarely, bloodstream infection (BSI) has another origin, or endocarditis can lead to central nervous system infection. Meningitis is rare and can follow respiratory tract infection, or it can occur as a complication of a cerebrospinal fluid shunt. Ventriculoperitoneal shunt infection with the *B. fragilis* group can have an enteric origin after perforation of the gut.[15]

At the stage of encephalitis, antimicrobial therapy can prevent the formation of abscesses. Once an abscess has formed, excision or drainage generally are needed, combined with 4 to 8 weeks of antibiotics. Administration of antibiotics for an extended period is an alternative approach that can replace surgical drainage in selected patients. Depending on the organism or organisms isolated and β-lactamase production, metronidazole, penicillins, and chloramphenicol frequently are chosen because of their spectrum and favorable pharmacodynamic profile.

Head and Neck Infections

Anaerobic bacteria are recovered from a variety of head and neck infections, especially chronic infections.[16]

Odontogenic Infections.

Most dental infections involve anaerobic bacteria, including *Prevotella* and *Porphyromonas* of oral flora origin.[17] These infections include pulpitis and periodontal and endodontal (gingivitis and periodontitis) infections, periapical and dental abscesses, and perimandibular space infections. Vincent angina (trench mouth or acute necrotizing ulcerative gingivitis) is an acute, destructive ulcerative gingivitis that causes severe pain and putrid breath odor. Oral fusospirochetes and other oral flora are causative.[18]

Peritonsillar, Lateral Pharyngeal, and Retropharyngeal Abscesses.

The predominant anaerobes isolated are *Prevotella, Porphyromonas, Fusobacterium,* and *Peptostreptococcus* spp. *Streptococcus pyogenes* is isolated in approximately one third of cases.[19] More than two thirds of abscesses contain β-lactamase–producing organisms.[19] Systemic antimicrobial therapy should be given in large doses; when pus is formed, adequate surgical drainage is needed. Untreated abscesses can rupture spontaneously into the pharynx and cause aspiration. Other complications are lateral extension or dissection into the posterior mediastinum and the prevertebral space.

Deep Neck Infections.

These infections generally follow oral, dental, and pharyngeal infections, usually are polymicrobial, and involve the organisms that caused the primary infection. Mediastinitis after esophageal perforation or extension of a retropharyngeal abscess or cellulitis often involves anaerobic bacteria, including AGNB.[20]

Chronic Otitis Media and Chronic Mastoiditis.

AGNB can be recovered from patients with chronic suppurative otitis media,[21] chronic mastoiditis,[22] or an infected cholesteatoma and can lead to complicating intracranial abscesses.

Sinusitis.

AGNB become involved when the sinusitis is chronic and oxygen levels decline.[23] Anaerobic bacteria are isolated from 10% of patients with acute maxillary sinusitis (most often in disease secondary to periodontal infection)[24] and in up to 67% of chronic infections (average of 3 species per aspirate).[25] Infection can spread through the anastomosing veins or contiguously, thereby causing orbital cellulitis, meningitis, cavernous sinus thrombosis, and epidural, subdural, and brain abscesses.[14]

Cervical Lymphadenitis and Cysts.

AGNB can be isolated in cervical lymphadenitis,[26] especially in association with dental, periodontal, or tonsillar infection. Thyroglossal duct cysts, cystic hygromas, branchial cleft cysts, laryngoceles, and dermoid cysts can become infected.[27]

Infection After Head and Neck Operations.

These infections follow exposure of the surgical site to the oropharyngeal flora. Infections generally are polymicrobial and therefore warrant the use of proper prophylaxis.[28]

Chronic Tonsillitis.

AGNB can be involved in acute tonsillitis, chronic tonsillitis, and their complications, including internal jugular vein thrombophlebitis. Evidence of pathophysiologic features of anaerobes in nonstreptococcal tonsillitis includes the following: reduction of fever and clinical symptoms in patients treated with metronidazole compared with untreated children[29]; a detectable immune response against AGNB in patients with tonsillitis, peritonsillar cellulitis or abscess, and infectious mononucleosis[30]; isolation of AGNB from the cores of tonsils of children with recurrent tonsillitis[23] and peritonsillar and retropharyngeal abscesses[31]; and isolation of aerobic and anaerobic β-lactamase–producing organisms from the tonsils of more than 75% of children with recurrent streptococcal tonsillitis.[32] The ability to measure β-lactamase activity in the core of tonsils and patients' responses to agents effective against β-lactamase–producing bacteria (i.e., clindamycin or amoxicillin plus clavulanic acid) support the role of AGNB in children in whom penicillin has failed to eradicate streptococcal tonsillitis.[32]

Pleuropulmonary Infections

Aspiration of oropharyngeal or gastric secretions and periodontal or gingival disease are risk factors for the development of anaerobic (including AGNB) pleuropulmonary infection. Infection can progress from pneumonitis to necrotizing pneumonia and abscess, with or without empyema. AGNB can be recovered from patients with community-acquired and nosocomially acquired aspiration pneumonia,[33] and as well as with pneumonia associated with tracheostomy[34] with and without mechanical ventilation, in which case AGNB generally are recovered along with Enterobacteriaceae, *Pseudomonas,* and *Staphylococcus aureus.* Anaerobes can be recovered in empyema associated with aspiration pneumonia, lung abscess, subdiaphragmatic abscess, and abscesses of dental or oropharyngeal origin.[35]

Management of these infections includes drainage of the pleural space when indicated and antimicrobial therapy.

Intra-Abdominal Infections

Intra-abdominal infections characteristically are biphasic; initial peritonitis is associated with *Escherichia coli* sepsis, and later intra-abdominal abscesses are caused by *B. fragilis*.[36]

Perforated appendicitis, inflammatory bowel disease with perforation, gastrointestinal operations, obstruction, infarction, and trauma often are predisposing factors to secondary peritonitis and intra-abdominal abscesses, which invariably are polymicrobial (average of 12 isolates).[37] The predominant isolates are AGNB (including *Biophila wadsworthia*).[38] Similar aerobic and anaerobic bacteria are found in pyogenic liver,[39] splenic,[40] pancreatic,[41] and retroperitoneal abscesses.[42] In neonates, peritonitis and abscesses often occur as a result of necrotizing enterocolitis.[43] Management of intra-abdominal infections requires the use of agents effective against aerobic and anaerobic pathogens, as well as surgical correction and drainage.[44] Single and easily accessible abscesses can be drained percutaneously.

Therapy directed at Enterobacteriaceae and AGNB can be achieved with combinations or single agents in certain circumstances.[44] Potential single agents could be a carbapenem (imipenem, meropenem) or a penicillin plus a β-lactamase inhibitor (e.g., piperacillin-tazobactam, ticarcillin-clavulanate). Combination therapy includes an anti-Enterobacteriaceae agent (e.g., aminoglycoside, fluoroquinolone, third-generation cephalosporin) plus an antianaerobic agent (e.g., metronidazole). The need to add amoxicillin or vancomycin routinely for *Enterococcus* therapy is controversial.

Antimicrobial prophylaxis before colonic surgical procedures could consist of an oral preparation such as erythromycin plus neomycin or a parenteral agent such as cefoxitin. The use of prophylaxis has reduced the rate of postsurgical wound infection.

Enterotoxigenic *B. fragilis* has been associated with acute diarrhea, colitis, and colonic inflammatory bowel disease.[45] Abdominal pain and nonfebrile inflammatory diarrhea are usual manifestations.[46]

Genital Tract Infections

Infections of the female genital tract are polymicrobial and include the following: bacterial vaginosis; soft tissue perineal, vulvar, and Bartholin gland abscesses; endometritis; pyometra; salpingitis; tubo-ovarian abscesses; adnexal abscesses; and pelvic inflammatory disease. The pelvic inflammatory disease category includes pelvic cellulitis and abscess, amnionitis, septic pelvic thrombophlebitis, intrauterine device–associated infection, septic abortion, and postsurgical obstetric and gynecologic infections.[1,2]

AGNB play a role in prostatic and scrotal infections including Fournier gangrene.[47] Therapy should include agents effective against all potential aerobic and anaerobic pathogens. Additionally, coverage against sexually transmissible pathogens should be provided.

Skin and Soft Tissue Infections

AGNB can cause superficial infections such as infected cutaneous ulcers, cellulitis, secondary diaper rash, gastrostomy or tracheostomy site wounds, infected subcutaneous sebaceous or inclusion cysts, eczema, scabies or kerion infections, paronychia, hidradenitis suppurativa, and pyoderma.[48] Subcutaneous tissue infections and postsurgical wound infection also can include skin flora and AGNB.[28,37] Such infections include cutaneous and subcutaneous abscesses, decubitus ulcers,[49] infected diabetic (vascular or trophic) ulcers, breast abscesses, bite wounds,[50] anaerobic cellulitis and gas gangrene, bacterial synergistic gangrene, infected pilonidal cyst or sinus, Meleney ulcers, and burn wound infection. Deeper anaerobic soft tissue infections include necrotizing fasciitis, necrotizing synergistic cellulitis, gas gangrene, and crepitus cellulitis.[51] These infections can involve only the fascia, the muscle surrounded by the fascia (inducing myositis and myonecrosis), or both the fascia and the muscle.

The organisms recovered from soft tissue infections vary according to the type and location of the infection and the circumstances leading to the infection. Wound and subcutaneous tissue infections and abscesses of the rectal area (decubitus ulcer, perirectal abscess) or infections originating from gut flora (e.g., diabetic foot infection) tend to yield colonic flora. Sites in and around the oropharynx (e.g., paronychia, bites) generally contain oral flora. Skin flora organisms such as *S. aureus* and *Streptococcus* or nosocomially acquired organisms (gram-negative aerobic bacilli) can be isolated at all body sites. In addition to oral flora, human bite infections often contain *Eikenella* species, and animal bite infections can include *Pasteurella multocida*.[50] Anaerobic infections (e.g., decubitus ulcers, diabetic foot ulcer) generally are polymicrobial and often are complicated by osteomyelitis or BSI. Deep tissue infections such as necrotizing cellulitis, fasciitis, and myositis often involve clostridia or *Streptococcus pyogenes* or are polymicrobial; they contain gas and grey, thin, putrid-like pus and are associated with BSI and substantial mortality rates.

Management of deep-seated soft tissue infection includes surgical debridement and drainage, improvement in the blood supply when indicated, and administration of hyperbaric oxygen, especially in patients with clostridial infection.

Osteomyelitis and Pyogenic Arthritis

Osteomyelitis is associated with AGNB in patients with peripheral vascular disease and decubitus ulcers and when infection occurs in long bones and in cranial and facial bones.[52] Osteomyelitis of cranial and facial bones generally is caused by spread from a contiguous soft tissue source or from sinus, ear, or dental infections. Osteomyelitis of long bones generally is caused by hematogenous spread, trauma, or the presence of a prosthetic device.

Recovery of AGNB is associated with certain settings: *Prevotella, Porphyromonas,* and *Fusobacterium* with skull osteomyelitis and bites; *B. fragilis* with vascular disease or neuropathy; and clostridia with long bone osteomyelitis, especially in wounds contaminated after trauma.[53]

Most cases of pyogenic arthritis resulting from anaerobic bacteria are monomicrobial and occur after hematogenous and contiguous spread, trauma, and arthritis associated with prosthetic joints. The predominant isolates are peptostreptococci and *Propionibacterium acnes* (often in prosthetic joint infection), *B. fragilis* and fusobacteria (often in infections of hematogenic origin), and clostridia (associated with trauma).

Bloodstream Infection

AGNB are responsible for up to 5% to 15% of BSIs. Common isolates are the *B. fragilis* group (60%–75% of isolates). The *B. fragilis* group and clostridia are associated with a gastrointestinal source, pigmented *Prevotella* and *Porphyromonas* and *Fusobacterium* are assocoiated with oropharyngeal and pulmonary sites, *P. bivia* and *P. disiens* are associated with the female genital tract, *P. acnes* is associated with foreign bodies, and peptostreptococci are associated with all sources, but especially with oropharyngeal, pulmonary, and female genital tract sources.[54]

Predisposing factors include the following: neoplasms; hematologic disorders; organ transplantation; recent gastrointestinal, obstetric, or gynecologic surgical procedures; intestinal obstruction; decubitus ulcers; dental extraction; diabetes mellitus; the postsplenectomy state; and the use of cytotoxic agents or corticosteroid therapy. Features typical of BSI with AGNB include metastatic lesions, hyperbilirubinemia, and suppurative thrombophlebitis. Shock and disseminated intravascular coagulation are less common compared with aerobic gram-negative BSI. The mortality rate is 15% to 30%, but it improves with early appropriate antimicrobial therapy and aggressive management of the root cause.

Anaerobic bacteremia in newborns is caused by AGNB, *Clostridium,* and *Peptostreptococcus* spp., and it is associated with perinatal maternal complications (primarily premature rupture of membranes and chorioamnionitis), prematurity, and necrotizing enterocolitis.[55]

Treatment

In most cases, surgical therapy is of critical importance. Surgical treatment includes draining abscesses, débriding necrotic tissues, identifying the primary source of infection, removing devitalized tissue, decompressing closed-space infections, and relieving obstructions. In selected cases, an abscess can be drained with the use of imaging modalities to guide catheter placement without surgical or laparoscopic intervention.[56] When surgical drainage is not performed, the infection can persist, and serious complications can develop. The duration of antimicrobial therapy for anaerobic infections generally is longer than that for infections with aerobic and facultative organisms.

Resistance to antimicrobial agents has a broad basis, but β-lactamase production has the most clinical significance. All *B. fragilis* group strains produce β-lactamase, as do many clinical isolates of *Prevotella, Porphyromonas, Fusobacterium, S. wadsworthensis,* and *Bacteroides splanchnicus,* and this feature renders these organisms resistant to penicillins. Agents active in vitro against β-lactamase–producing AGNB include metronidazole, chloramphenicol, clindamycin, cefoxitin, carbapenems, and combinations of a penicillin and a β-lactamase inhibitor (e.g., ampicillin-sulbactam, ampicillin-clavulanate, ticarcillin-clavulanate, and piperacillin-tazobactam) (see Chapter 187). Large databases show the following resistance rates of the *B. fragilis* group in the United States and Europe, respectively: clindamycin, >35% and 32%; moxifloxacin, 32% and 14%, cefoxitin, 10% and 9%; tigecycline, 4%, and 5%; ampicillin-sulbactam/amoxicillin-clavulanate, 3% and 10%; piperacillin-tazobactam, <1% and 3%; meropenem/imipenem, <1% and 1%; and metronidazole, <1%.,[4,57] *Prevotella, Fusobacterium,* and *Porphyromonas* species isolates are more likely than *B. fragilis* group to be susceptible to clindamycin. Although antibiotic susceptibility of *P. melaninogenica* and *P. intermedia* can vary geographically, most of these organisms are β-lactamase producing (penicillin resistant), 10% are resistant to clindamycin, and none is metronidazole resistant.[58] The *B. gracilis* group, found primarily in gingival crevices, is more likely than *B. ureolyticus* (now *Campylobacter ureolyticus*) to be recovered from serious, deep infections and is more resistant to antibiotics (e.g., clindamycin and metronidazole), but it is sensitive to gentamicin[59]; *Sutterella wadsworthensis* is predominantly responsible for resistant organisms in the former *B. gracilis* group, with clindamycin resistance rates of 15% to 30%[60] in some areas. Despite difficulties in breakpoint determinations and exact clinical correlation with in vitro results, agents active in vitro are more likely to be associated with a good clinical outcome and vice versa.[59,61] The choice of agents depends on the site and stage of infection and the probable coinfecting pathogens. Although early infection such as aspiration pneumonia can be treated effectively with agents active primarily against facultative and some anaerobic organisms (not necessarily *Bacteroides* or *Prevotella*), necrotizing infection or abscess is best treated with specifically directed therapy.

The role of hyperbaric oxygen in the treatment of anaerobic infections remains unclear, with some suggestion of benefit as adjunctive therapy to surgical debridement and antibiotics.[62,63]

Prevention

Elimination of acute infection can prevent chronic infections in which AGNB and other anaerobes predominate. When anaerobic infections are anticipated complications of surgical procedures at heavily colonized mucosal sites, proper antimicrobial prophylaxis reduces the infection rate. Early treatment of conditions that may lead to anaerobic infection also can reduce this rate. Preventing aspiration of oral flora by improving the patient's neurologic status, suctioning, improving oral hygiene, and maintaining lower stomach pH can reduce the risk of aspiration pneumonia and its complications.

Skin and soft tissue infections can be prevented by irrigation and debridement of wounds and necrotic tissue, drainage of pus, and improvement of perfusion. Prophylaxis generally is instituted preoperatively when contamination by normal flora is expected at the operative site.[64] Cefazolin is effective prophylaxis at sites distant from the oral or rectal areas. Cefoxitin is the drug of choice in procedures that involve the oral, rectal, or vulvovaginal surfaces.

Fusobacterium Species

Neil Rellosa, Jennifer Vodzak

Fusobacteria are non–spore-forming, nonmotile, pleomorphic, gram-negative (Fig. 193.1), obligate anaerobic bacilli that can cause a wide spectrum of human disease ranging from mild pharyngitis to sepsis, and these organisms are most notorious for causing septic thrombophlebitis of the internal jugular vein, commonly referred to as Lemierre syndrome.[1–15] *Fusobacterium* infections in children and adolescents often are associated with abscess formation and intracranial complications.[16] *F. nucleatum* and *F. necrophorum* subspecies *funduliforme* are the most common fusobacteria identified in human disease.[1,6,17,18]

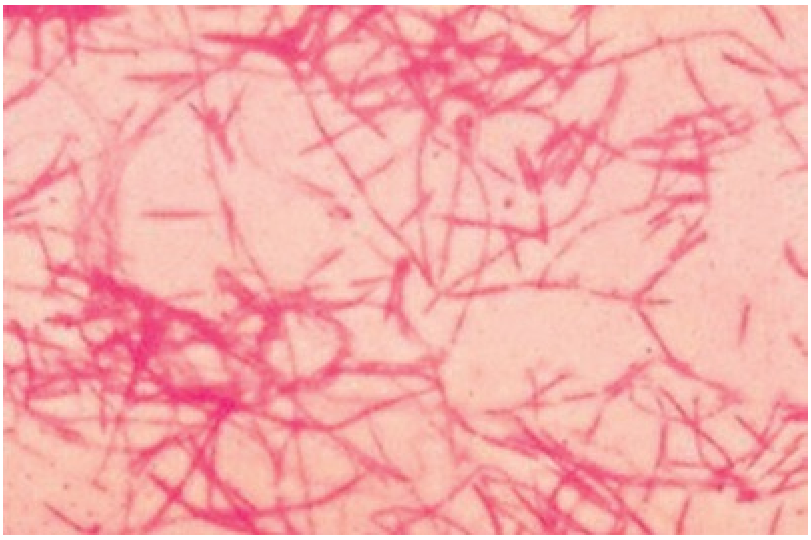

FIGURE 193.1 **Gram stain of *Fusobacterium nucleatum*, magnification 1000×.** (From Baron EJ, Peterson LR, Finegold SM [eds]. Bailey and Scott's Diagnostic Microbiology, 8th ed. St. Louis, Mosby, 1990.)

Description of the Pathogen

The genus *Fusobacterium* includes 9 disease-causing species that are part of the normal flora of the human oropharynx and the upper respiratory, gastrointestinal, and female genitourinary tracts: *F. nucleatum* (subspecies *nucleatum, polymorphum, vincentii, animalis, fusiforme,* and *canifelium*[6]), *F. necrophorum* (subspecies *necrophorum* and *funduliforme*), *F. ulcerans, F. gonidiaformans, F. mortiferum, F. naviforme, F. necrogenes, F. russii,* and *F. varium*.[6,7,18–26] Because molecular techniques are redefining the taxonomy and role of fusobacteria as commensals and pathogens, this compilation is evolving.[6,25]

Unlike other anaerobes, *F. necrophorum* produces lipopolysaccharide, which contributes to its intrinsic virulence.[4,5] Overall, one third of fusobacterial infections are polymicrobial,[27] and animal studies demonstrated increased virulence of *F. necrophorum* in the presence of fecal organisms.[28] Additional, less well-characterized virulence factors include production of leukocidins, hemolysins, lipases, DNases, hemagglutinins, β-lactamases (by *F. nucleatum*), and the ability to aggregate platelets (*F. necrophorum*).[4,5,14,18] Molecular thrombophilic predisposition has been identified in children with invasive fusobacteriosis.[29–32] Whole-genome sequencing of a diverse set of *Fusobacterium* spp. revealed that actively invading species have larger genomes than passively invading species and possess a complement of genes that have evolved to enable host cell adherence and invasion.[33] A single nucleotide polymorphism in the toll-like receptor 5 gene was found in 1 affected child,[29] a finding suggesting that underlying host factors also may predispose to infection.

Epidemiology

Well recognized in the preantibiotic era, invasive fusobacteriosis was rarely reported after the advent of antibiotic therapy for pharyngitis,[34] and it became a forgotten disease.[5] Since the 1990s, both incidence and disease reporting have been increasing.[4,35–37] The increase in incidence may be the result of decreased empiric use of antibiotics for sore throat, increased use of corticosteroid therapy for mononucleosis or sore throat, superior blood culture methods, improved techniques for diagnosis of anaerobic infections, and use of non–culture-based molecular diagnostic tools.[1,4,5,14] Fewer tonsillectomies also could contribute to the increased incidence.[4,5] However, a Swedish study in adolescents and adults found persistent pharyngeal colonization with *F. necrophorum* despite tonsillectomy (30% versus 16% in pre tonsillectomy versus posttonsillectomy throat cultures).[38] Estimates of disease incidence range from 0.8 to 3.6 cases per million people.[27,35,39] A prospective study in Denmark demonstrated an incidence of Lemierre disease of 14.4 cases per million people 15 to 24 years of age.[39] The infection may have a peak in late winter.[34] Boys and men are more commonly afflicted.[1–4,34]

Three age-related disease patterns are observed for fusobacteriosis (Table 193.1).[1,4,39,40] Localized head and neck disease tends to arise from the middle ear (and occasionally, cervical lymph nodes) in young children, the throat and tonsil in adolescents, and the sinuses and carious teeth and gums in adults.[40] Similarly, invasive or disseminated fusobacterial infection tends to vary with age. Children tend to develop infection, often associated with otitis media,[40] that can disseminate systemically but more often results in intracranial complications.[1,16,41] Otogenic Lemierre disease was reported in patients 2 months to 51 years of age (median, 5 years), whereas pharyngitis-associated Lemierre disease occurred in patients 8 months to 63 years of age (median, 19 years).[1] Other investigators have noted peak ages for Lemierre disease of 16 to 23 years[36] (median age range, 17–21.5 years).[27,42,43] In another series of cases in patients ranging in age from 2 months to 78 years, distribution of cases was 51%, 20%, and 8% in the second, third, and first decades of life, respectively.[2] In a prospectively collected series of 391 isolates of *F. necrophorum* from localized and disseminated infections, 343 isolates had subspeciation performed; >99% were *F. necrophorum* subspecies *funduliforme,* and a single isolate was *F. necrophorum* subspecies *necrophorum*.[39,40]

TABLE 193.1

Prospectively Collected Series of 388 Cases of *Fusobacterium necrophorum* Infection

Classification	Source of Infection	Number of Cases	Age Range (Yr)	Median Age (Yr)
Localized disease (n = 288)	Otogenic source	7	0–26	4
	Cervical lymphadenitis	9	0–46	3
	Tonsillitis	26	13–57	20
	Peritonsillar abscess	215	4–72	19
	Sinus- or teeth-associated source	10	29–73	44
	Localized disease caudal to the head and neck	21	9–83	38
Disseminated disease (n = 100)	Otogenic Lemierre disease	5	0–16	2
	Oropharyngeal-associated Lemierre disease	37	6–66	20
	Disseminated disease originating from sinus or teeth	16	7–89	24–55[a]
	Disseminated disease originating from the gastrointestinal tract	30	5–89	61
	Disseminated disease originating from the genitourinary tract	6	25–96	78
	Disseminated disease originating from an unknown focus	6	66–87	76

[a] Group subdivided with 2 medians reported in Hagelskjær Kristensen L, Prag J. Lemierre's syndrome and other disseminated *Fusobacterium necrophorum* infections in Denmark: a prospective epidemiological and clinical survey. Eur J Clin Microbiol Infect Dis 2008;27:779–789.

Data from Hagelskjær Kristensen L, Prag J. Lemierre's syndrome and other disseminated *Fusobacterium necrophorum* infections in Denmark: a prospective epidemiological and clinical survey. Eur J Clin Microbiol Infect Dis 2008;27:733–739.

Clinical Manifestations

Fusobacterial infection can be divided into invasive disease and localized disease (exemplified by peritonsillar abscess); localized disease occurs more frequently although it is reported less often. Lemierre disease can be diagnosed by clinical manifestations.[44] The most common symptoms and findings include sore throat, fever, rigors, neck mass, neck pain, trismus, tenderness along the neck vasculature, anorexia, malaise, cough, chest pain, shortness of breath, and prostration.[1–5] Typically, sore throat is followed by fevers and rigors (a distinctive feature) on the fourth or fifth day and by painful swelling in the neck (often mistakenly attributed to lymphadenopathy, which is tender but rarely is painful).[1–5] Phlebothrombosis leads to septic embolization to the lungs, but metastatic foci of infection also can occur in joints, muscles, bones, liver, skin, spleen, and endocardium.[1]

Otogenic disseminated fusobacteriosis more often results in intracranial complications, including meningitis[16,41,45–51] and vascular thrombosis,[16,50,51] but it rarely results in internal jugular involvement.[51] Meningitis also can complicate fusobacterial sinusitis in older children and adults,[52–54] as can brain abscesses, but brain abscesses are more often secondary to periodontal disease with bloodstream infection (BSI).[55–57]

Bloodstream infection in adults usually is associated with predisposing conditions.[39,58] Bloodstream infection has been reported in healthy[59] and neutropenic[3] children.

The most common clinical manifestations of fusobacterial infection are pharyngitis (especially recurring, persisting, and poorly responsive to typically prescribed antibiotic therapy),[21,60–62] tonsillitis,[24] and peritonsillar abscess.[40,63–65] Using appropriate culture and polymerase chain reaction (PCR)–based techniques, *F. necrophorum* has been identified in 10% to 21% of cases of persistent sore throat or tonsillitis.[21,24,60,61] In a prospective Danish study, *F. necrophorum* was identified in 21% of 1001 peritonsillar abscesses.[40] In a Finnish study, *F. nucleatum* and *F. necrophorum* were isolated from 26% and 38% of peritonsillar abscesses, respectively (compared with *Streptococcus pyogenes* from 46%).[63] In another Danish series of 847 patients with peritonsillar abscess, *F. necrophorum* was the most frequent cause (23%) compared with 17%

for *S. pyogenes*.[65]

Lung and liver abscesses are recognized complications of Lemierre syndrome,[66] although isolated localized infection can occur even in immunocompetent patients.[67–69] Less common manifestations of fusobacteriosis include pyogenic arthritis (most frequently involving the knee, hip, ankle, shoulder, elbow, sacroiliac, or sternoclavicular joint),[41,70–72] osteomyelitis (affecting facial bones more often than the vertebrae, pubic bone, or extremities),[72–75] and spondylodiscitis.[76,77] Wound and zoonotic infections occur rarely.[4,6,18] Single cases of multiple cranial nerve impairments[71] and sensorineural hearing loss[41] have been reported. Finally, *F. necrophorum* has been implicated in orofacial gangrene (cancrum oris or noma)[78–80] and tropical ulcer.[20] Bacterial 16S ribosomal RNA gene sequencing of appendiceal samples from children with acute appendicitis and controls has suggested a possible pathologic role of *Fusobacterium* species.[81]

Laboratory Findings and Diagnosis

Laboratory findings are nonspecific[1–3]; leukocytosis with increased band forms is common, as is elevated C-reactive protein.[2,3,39,40,65] Abnormal results of hepatic biochemical tests, particularly hyperbilirubinemia, are found in 11% to 49% of patients with Lemierre disease.[27,39,43] Less commonly, thrombocytopenia and evidence of disseminated intravascular coagulopathy are present in Lemierre disease.[39,71] Culture confirmation of *Fusobacterium* infection requires adequate or protected specimen collection and optimized transport, culture medium, and identification. Increasingly, PCR-based molecular methods including broad-range 16S (small subunit) ribosomal DNA PCR are used to confirm fusobacterial infections.[17,21,24,82,83]

Imaging studies generally are helpful to confirm clinical suspicion and evaluate for intravascular, local, and metastatic complications (Fig. 193.2).[84] Multiple imaging modalities may be employed because patients often are quite ill, and the extent of the disease may not be established on clinical grounds alone.

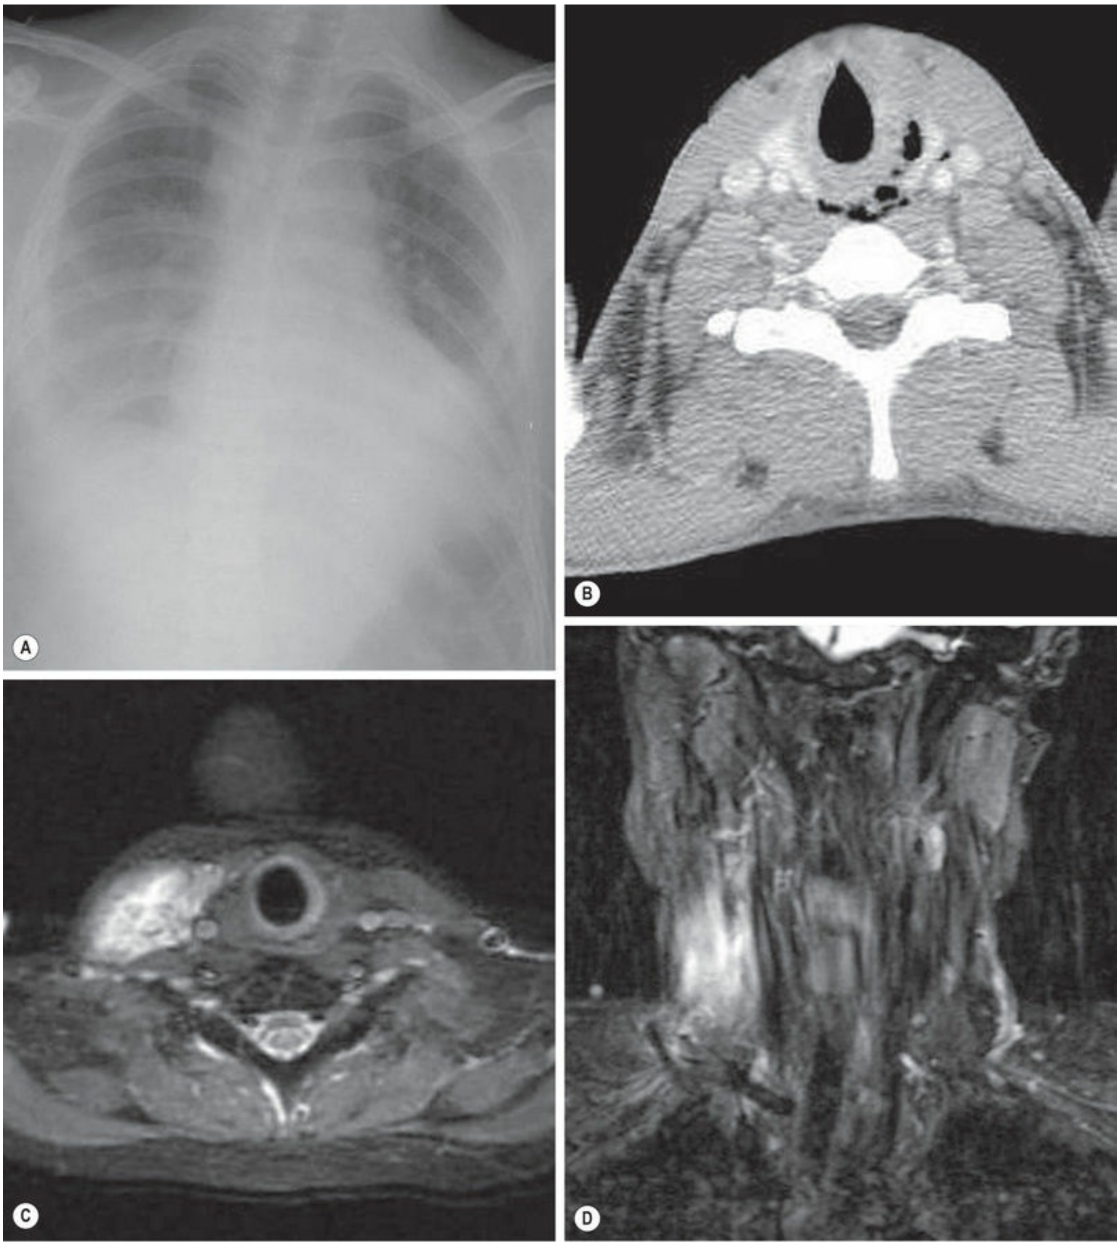

FIGURE 193.2 **Images of 2 adolescents with Lemierre disease. (A) Chest radiograph shows left lower lobe consolidation, bilateral pleural effusions, and widened mediastinum. (B) Axial computed tomography of the neck shows left-sided soft tissue swelling and perivascular gas, which extended into the mediastinum. (C) Axial and (D) coronal magnetic resonance imaging of the neck in another patient shows right-sided soft tissue swelling, perivascular edema, and filling defects in the internal jugular vein.** (Courtesy of S. Underberg-Davis and S. Schonfeld, the Children's Hospital at St. Peter's University Hospital, New Brunswick, NJ.)

Treatment

In a series from Wales conducted before 2000, 15% of *F. necrophorum* isolates were resistant to erythromycin, 2% were resistant to penicillin, and 1% to tetracycline.[36] Increasingly, β-lactamase–

producing strains of *F. necrophorum* and *F. nucleatum* are reported.[85,86] A *Fusobacterium* isolate with carbapenem resistance has been reported, with clinical failure during meropenem monotherapy.[87] Metronidazole resistance has not been reported among isolates of *Fusobacterium*.[84,86] Most experts recommend antibacterial therapy with metronidazole (in combination with a penicillin for severe or invasive disease); additionally, clinical outcomes (particularly of central nervous system disease) seem to be improved when metronidazole is included.[1,4,86] Combination therapy is preferable to monotherapy for serious infection because cultures may not be properly obtained, infections occasionally are polymicrobial, and infection with other organisms can mimic fusobacteriosis.[1,4,86] The median duration of fever after initiation of appropriate antibiotic therapy for Lemierre disease is 8 to 12 days.[4] The duration of reported therapy ranges from 9 to 84 days, with a median of 42 days,[13] but some experts recommend a 2- to 3-week course of antibiotics parenterally if the clinical course is reassuring, followed by oral therapy to complete 6 weeks.[1] Important adjunctive therapy includes operative intervention as necessary to drain abscesses.[4] Ligation of the thrombosed internal jugular vein rarely is necessary in the antibiotic era, unless the thrombus progresses or repeated embolization occurs despite medical therapy.[88] The role of anticoagulation remains controversial, with inadequate data to make recommendations.[30–32,88]

Special Considerations

F. nucleatum infections have been implicated in preterm delivery and chorioamnionitis.[3,89-91] In 1 series, 36% of women with preterm delivery (compared with none who delivered at term) had *F. nucleatum* isolated from vagina specimens.[89] *F. nucleatum* is the organism most frequently isolated from the amniotic fluid of women with preterm labor and intact membranes.[90,91] *F. nucleatum* subspecies *nucleatum* and *vincentii* colonize the oral cavity rather than the lower genital tract, a finding suggesting that hematogenous infection of the amniotic fluid and resultant preterm labor were the result of periodontal disease.[90,91]

Prevention

Most fusobacterial infections cannot be prevented. However, optimized oral hygiene can be recommended. Furthermore, a thoughtful approach to the patient with throat infection seems prudent. Withholding empiric antibiotic therapy for simple pharyngitis in the absence of evidence of streptococcal disease is appropriate. However, patients (particularly adolescents and young adults) without coryza who have a high fever lasting >3 days (especially with rigors) with neck pain, swelling, or tenderness, or who have a severe sore throat lasting >3 days, require special consideration.[5,62]

Acknowledgment

The authors acknowledge substantial use of material of Robert Tolan, MD, the author of this chapter in the previous edition, and the pediatric infectious diseases community mourns his untimely death.

Anaerobic Cocci

Debrah Meislich, Anat R. Feingold

The anaerobic cocci are major components of the normal microbiota of the mouth, upper respiratory tract, gastrointestinal tract, vagina, and skin.[1] Gram-positive cocci and gram-negative cocci (*Veillonella* spp.) are the anaerobic bacteria most commonly isolated from clinical specimens.[1–3] Traditional methods of isolating anaerobes is time consuming and can require multiple subcultures and biochemical analyses; the use of inappropriate culture and transport methods further reduces the ability to isolate anaerobic cocci.[4] Newer techniques such as polymerase chain reaction 16S (small subunit) ribosomal RNA sequencing and matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) mass spectrometric analysis more rapidly and sensitively identify anaerobes from clinical specimens,[1,5,6] and these techniques have added to our understanding of the role of these anaerobes in human infections.[7]

Compared with all gram-positive anaerobes, the gram-positive cocci are most prominent, accounting for approximately ≥25% of all anaerobes grown from clinical specimens.[1] Gram-positive anaerobic cocci are most often a part of the following infections: deep soft tissue, central nervous system, intra-abdominal, bone and joint, and gynecologic. Although anaerobic bloodstream infection (BSI) is rare in children, anaerobic cocci have been isolated, especially in cases of polymicrobial BSI.[8] The classification of anaerobic gram-positive cocci is changing continually as new species are added or reclassified.[7] At present, 6 clinically significant genera of anaerobic gram-positive cocci are recognized: *Peptostreptococcus*, *Finegoldia*, *Parvimonas*, *Anaerococcus*, *Petoniphilus*, and *Peptococcus*.[7] The first 5 genera are most often associated with infection.[1] *Finegoldia magna* is more often isolated in pure culture from clinical infection sites.[6,8] Of the 3 genera of anaerobic gram-negative cocci, only 1, *Veillonella,* is found in clinical isolates. *Veillonella parvula* is a commensal in the oral, gastrointestinal, respiratory, and female genital tract biota, and it is the species most commonly isolated from human specimens.[7,9] In a 20-year review documenting anaerobes isolated from children with clinical infections, *Veillonella* spp. were recovered most often from abscesses, aspiration pneumonias, burns, bites, and sinuses.[10] Most often a part of a polymicrobial infection, *Veillonella* was isolated alone in 5% of these children.[10] *Veillonella parvula* causes serious infection occasionally in association with malignant disease, corticosteroid use, previous surgical procedures, indwelling devices, or intravenous drug use and rarely in otherwise healthy people.[10,11]

Pathophysiology and Predisposing Conditions

Infection by anaerobic cocci occurs at sites contiguous to their commensal habitats. Anaerobic coccal infections can occur in all body sites, including the central nervous system, head, neck, chest, abdomen, pelvis, skin, and soft tissues.[3,12] These organisms can be sole pathogens in osteoarticular infections, occasionally in soft tissue infections, and in BSI.

Synergy has been found between anaerobic gram-positive cocci and their aerobic and anaerobic counterparts.[13–15] Synergy is indicated by mutual enhancement of the induction of sepsis, higher mortality rates, greater ability to induce abscesses, and enhancement of growth of the bacteria in mixed infection. The ability of anaerobic gram-positive cocci to produce capsular material is an important virulence mechanism.[13,16] *Finegoldia magna* and *Veillonella* spp. produce biofilms and form tighter aggregates when these organisms are grown synergistically with other anaerobes.[17] *Parvimonas* and *Finegoldia* also produce surface proteins that function as virulence factors.[1]

Clinical Manifestations

Central Nervous System Infections.

Anaerobic gram-positive cocci can be isolated from subdural empyema and brain abscesses that develop as sequelae of chronic infections of the ear, mastoid, sinuses, teeth, and pleuropulmonary sites.[18,19] An anatomic abnormality leading to communication with a mucosal site should be sought if a predisposing infection is not found. Anaerobic gram-positive cocci have been isolated from 46% of brain abscesses. *Peptostreptococcus* and *Veillonella* are rare causes of meningitis in children.[19] An infant with *Veillonella* and *Bifidobacterium* meningitis was found to have a sacral dimple and tethered spinal cord as a predisposing condition.[20]

Upper Respiratory Tract and Dental Infections.

Anaerobic gram-positive cocci frequently are recovered from patients with acute and chronic upper respiratory tract infections. The role of anaerobic bacteria in children with tonsillitis is unclear because these organisms are part of the normal flora of the pharynx, tonsils, and adenoids.[21] However, gram-positive anaerobic cocci play a prominent role in peritonsillar abscesses. In 1 study, *Peptostreptococcus* was isolated in 27% of aspirated specimens from patients with peritonsillar abscess.[21] Peptostreptococci are the predominant anaerobes recovered from aspirates in children with the following: chronic otitis media with effusion; retropharyngeal, parapharyngeal, and deep neck abscesses; and chronic sinusitis and chronic mastoiditis.[22,23] Peptostreptococci are isolated commonly with *Staphylococcus aureus* from children with parotitis.[24] *Parvimonas micros*, a part of the commensal flora of the gingival crevice, also is the most common isolate in polymicrobial periodontitis. *P. micros* is prominent in polymicrobial apical abscesses.[1] When polymerase chain reaction techniques were used, *P. micros* was the most prominent anaerobic gram-positive coccus detected in young adults with odontogenic infections.[4]

Anaerobic Pleuropulmonary Infections.

Anaerobic gram-positive cocci often are involved in pulmonary infections, especially pulmonary infections associated with odontogenic infections or as a consequence of aspiration of oropharyngeal secretions or gastric contents.[19] Sampling by transtracheal aspiration, aspiration through a double-lumen catheter, or direct lung puncture is required to obtain meaningful specimens. In a clinical study of patients with pleural empyema, 4 of whom were children <18 years of age, gram-positive anaerobic cocci were isolated in approximately 35% of patients (*F. magna* and *P. micros* each in 8%).[25]

Intra-Abdominal Infections.

Anaerobic gram-positive cocci can be recovered from 3% to 20% of specimens from patients with intra-abdominal infections, such as peritonitis and liver, spleen, and abdominal abscesses,[26,27] concurrently with other organisms of intestinal origin, including *Escherichia coli, Pseudomonas aeruginosa*, streptococci, enterococci, and the *Bacteroides fragilis* group.[27,28]

Female Pelvic Infections.

Anaerobic gram-positive cocci can be isolated from 25% to 50% of patients with endometritis, pyoderma, pelvic abscess, Bartholin gland abscess, postsurgical infections of the pelvis, and pelvic inflammatory disease. Anaerobic gram-positive cocci also can cause BSI in septic abortion. *Peptostreptococcus anaerobius* is isolated most commonly in these infections. Anaerobic gram-positive cocci generally are found with *Prevotella* species.[19] The presence of *Prevotella bivia* creates an environment that facilitates growth of *P. anaerobius* and is found in bacterial vaginosis.[1]

Osteomyelitis and Arthritis.

When anaerobes cause osteomyelitis or arthritis, gram-positive cocci account for 40% and 20% of isolates, respectively.[29] In longitudinal studies that included children and adults, anaerobic gram-positive cocci, especially *F. magna*, were predominant especially in patients with postsurgical or posttraumatic pyogenic arthritis.[30] Anaerobic osteomyelitis usually follows spread from a contiguous infection rather than spread through the hematogenous route.[31] Anaerobic gram-positive coccal osteomyelitis has been associated with bites, decubitus ulcers, and paronychiae.[30] Most osteoarticular infections follow orthopedic surgical procedures and placement of prosthetic material. In a 20-year review in children with osteomyelitis whose specimens were sent for anaerobic culture, *Veillonella* was isolated in 3.8%.[10]

Skin and Soft Tissue Infections.

Anaerobic gram-positive cocci often are recovered in polymicrobial skin and soft tissue infections in combination with other organisms specific to the site or setting. Such infections include necrotizing synergistic gangrene, necrotizing fasciitis,[32] decubitus ulcers,[33] paronychia,[34] burns,[35] human or animal bite infections,[36] infected cysts,[37] and abscesses of the breast,[38] rectum, and anus.[39] Anaerobic gram-positive cocci are more often isolated from soft tissue infections in and around the oropharynx.[19] *F. magna* is highly prevalent in patients with chronic wounds.[1]

Bloodstream Infections.

Anaerobic bacteremia is uncommon in pediatric patients, and anaerobic gram-positive cocci account for approximately 10% of isolates from patients with clinically significant anaerobic BSI.[40,41] *Veillonella* endocarditis is reported in adolescents and young adult intravenous drug users.[9] The most common sources of BSI are oropharyngeal, pulmonary, female genital tract, abdominal, and skin and soft tissue infections. The most frequent predisposing conditions are malignant disease, recent surgical intervention (gastrointestinal, obstetric, or gynecologic), immunosuppression, intravenous drug use, and dental procedures. Neonatal anaerobic BSI caused by *Peptostreptococcus* and *Veillonella* is reproted.[40]

Treatment

Infection usually is polymicrobial, and treatment is empiric, without laboratory confirmation of anaerobes or susceptibility testing.[11,42] Knowledge of trends of antimicrobial resistance comes from multicenter and longitudinal surveys.[8,43–47] Most anaerobic gram-positive coccal infections can be treated with penicillin G. A 2008, large multicenter European report noted that 7% of the gram-positive anaerobic cocci isolated from clinical specimens were resistant to penicillin.[48] Most resistant strains were *F. magna*. All clinical isolates were susceptible to metronidazole, vancomycin, imipenem, and linezolid.[48] A 2010 to 2011 multicenter study in Canada found ≤2% of the anaerobic cocci resistant to penicillin. Of 9 *Veillonella* isolates tested, one half were penicillin resistant.[44] European surveys document metronidazole resistance of anaerobic gram-positive cocci ranging from 6% to 30%.[46,47] Clindamycin-resistant gram-positive anaerobic cocci are isolated from 3% to 23% of clinical specimens.[44–47,49] These surveys also reveal trends in fluoroquinolone resistance of anaerobic gram-positive cocci. Although 1 study found moxifloxacin more potent than ofloxacin and ciprofloxacin with no moxifloxacin-resistant organisms,[49] a Belgian multicenter survey found only 68% moxifloxacin susceptibility among anaerobic cocci isolates.[50] A US study of 31 isolates of anaerobic gram-positive cocci found no resistance to meropenem, ampicillin-sulbactam, piperacillin-tazobactam, or ceftolozane-tazobactam, but approximately 10% resistance to moxifloxacin.[51] Linezolid has excellent activity against these organisms in vitro.[38,51]

In mixed infection with β-lactamase–producing bacteria, "susceptible" anaerobic gram-positive cocci can survive penicillin or cephalosporin therapy because of inactivation by the free enzyme. In such instances, agents with a wider spectrum of activity may be more effective.

In most cases, surgical drainage of abscesses, debridement of necrotic tissues, and removal of foreign material are critical. Without surgical drainage, infection can persist, and serious complications can develop.

Duration of therapy for anaerobic infections generally is prolonged and must be individualized. In some cases, the treatment course is 6 to 8 weeks, but it can be shortened following early, complete surgical management.

Anaerobic Gram-Positive Nonsporulating Bacilli (Including *Actinomyces*)

Anat R. Feingold, Debrah Meislich

Anaerobic gram-positive, nonsporulating bacilli of clinical significance include *Actinomyces, Bifidobacterium, Eubacterium, Lactobacillus, Mobiluncus,* and *Propionibacterium. Actinomyces* and *Propionibacterium* are the most common clinical pathogens and can be differentiated by biochemical reactions and metabolic products. Both pathogens show indole-positive reactions. Typically, *Propionibacterium* produces copious amounts of propionic acid and acetic acid, whereas *Actinomyces* produces acetic acid in addition to succinic and lactic acid. *Actinomyces* and *Propionibacterium* do not have mitochondria or a nuclear membrane. *Actinomyces* has diaminopimelic and muramic acid in the cell wall, whereas *Propionibacterium* has lysine. The genus *Mobiluncus* consists of gram-variable or gram-negative, curved rods with tapered ends, sometimes occurring in pairs with a gull wing appearance.

Previously aligned with Bacteroidaceae, *Mobiluncus* is more closely related to *Actinomyces.*

Propionibacterium Species

Propionibacterium spp. are pleomorphic, occasionally branching, anaerobic aerotolerant, diphtheroid, gram-positive bacteria. *P. acnes* is an important part of the normal flora of human skin, and it lives in and around sweat glands and sebaceous glands. Newer genomic, transcriptomic, and phylogenetic studies have allowed better understanding of this pathogen's importance as the causes of chronic and recurrent infection.[1] *P. acnes* is present in a biofilm with reduced metabolic activity in medical device–related infections and is most common in children with altered host defenses.[1] Predisposing conditions include a history of surgical manipulation, the presence of a foreign body or medical device, trauma, malignant disease, and primary or acquired immunodeficiency.[2] *Propionibacterium* spp.[3] (especially *P. acnes*) can cause bloodstream infection in immunocompromised people. *P. acnes* is catalase positive and causes pneumonia in children with chronic granulomatous disease,[4] as well as the following infections: endocarditis in patients with prosthetic or damaged heart valves[5]; conjunctivitis in contact lens wearers; and infections related to ventriculoperitoneal (VP) shunts, prosthetic joints, peritoneal dialysis, or intravascular catheters. *P. acnes* osteomyelitis most often follows orthopedic surgical procedures or instrumentation and placement of hardware (e.g., following spinal fusion).[6] Infections can be divided into early (first postoperative month) or late infections. Although *P. acnes* and *Staphylococcus epidermidis* are the most common bacterial causes of late postoperative infections,[7] *P. acnes* also is found in 10% to 40% of early postoperative infections.[6]

P. acnes causes inflammation of acne lesions.[7] It causes host proinflammatory activity, thus targeting molecules involved in innate cutaneous immunity, keratinocytes, and sebaceous glands of the pilosebaceous follicle and leading to the development of comedones.[8] In otherwise healthy adolescents with moderate to severe acne, *P. acnes* can be a rare cause of osteomyelitis, even in the absence of orthopedic surgical procedures or instrumentation.[9] *P. acnes* also can cause delayed VP shunt infection identified only when cerebrospinal fluid (CSF) and shunt catheters routinely are cultured anaerobically. *P. acnes* VP shunt infections more often follow valve puncture or distal catheter revision for distal obstruction. Compared with other causes of infection, children with *P. acnes* VP shunt infections tend to be less systemically ill, and they have only mild CSF pleocytosis and minor changes in CSF glucose and protein concentrations. Because of the slower rate of growth of *P. acnes*, CSF and catheter tips must be incubated for 5 to 7 days anaerobically when this organism is suspected.[10–12] P. *acnes* can be isolated alone, but more commonly it is mixed with other aerobic or anaerobic bacteria in the following infections: brain abscesses; subdural empyema; parotid, pulmonary, or dental infections, peritonitis; and osteomyelitis.[2] Isolation, however, most frequently represents skin contamination of cultures. Repeated isolation or visualization of *Propionibacterium* on Gram stain is required to identify true infection.

Surgical debridement, incision and drainage, and removal of foreign material are important in the management of *Propionibacterium* infections. Topical and oral antibiotics play a role in the treatment of moderate to severe acne. One study of children and adults with moderate to severe acne found that antibiotic-experienced (in the preceding 2–6 months) patients were more likely to be colonized with *P. acnes* resistant to clindamycin, erythromycin, and tetracycline.[13] The rate of antibiotic resistance, especially to macrolides and tetracyclines, has increased since 2000.[1] When nonskin clinical isolates of *P. acnes* were examined for antimicrobial susceptibility, approximately 3% were resistant to tetracycline, 15% to clindamycin, and 18% to erythromycin. No isolate was resistant to linezolid, penicillin, or vancomycin.[14] Metronidazole does not have predictable activity against *Propionibacterium* and cannot be used for therapy.[15]

Actinomyces Species

Actinomyces spp. are filamentous, branching, gram-positive, pleomorphic, non–spore-forming, catalase-negative, anaerobic or microaerophilic/capnophilic bacilli. Although many species have been associated with disease in humans, actinomycetes usually are soil dwelling organisms.[16] *Actinomyces* cannot be distinguished from *Nocardia* on Gram stain.[17] However, *Nocardia* spp. grow aerobically and stain with acid-fast technique, and *Actinomyces* spp. do neither. With the use of 16S (small subunit) ribosomal RNA (16S rRNA) sequencing, at least 21 species of *Actinomyces* have been identified in humans. *A. israelii* is the predominant disease-causing species (median, 73% of cases), although other *Actinomyces* spp., including *A. naeslundii* (the second most frequent *Actinomyces* sp.)[16] *A. meyeri, A. odontolyticus, A. gerencseriae,* and *A. viscosus,* as well as *Propionibacterium propionicum,* also have been implicated.[18,19] Many different *Actinomyces* spp. are associated increasingly with infections at many body sites, and currently, 25 *Actinomyces* spp. have been described from human material.[20] Most actinomycotic infections are polymicrobial, involving other aerobic and anaerobic bacteria. Coisolates depend on the source or site of infection and include *Aggregatibacter* (formerly *Actinobacillus*) *actinomycetemcomitans, Eikenella corrodens, Bacteroides, Fusobacterium, Capnocytophaga,* aerobic and anaerobic streptococci, *Staphylococcus,* and Enterobacteriaceae.

Pathogenesis

Actinomyces spp. generally have low virulence and are part of the normal flora of the mouth, other sites in the gastrointestinal tract, and the female genital tract. *Actinomyces* spp. are prevalent in the mouth from infancy and are recoverable from periodontal pockets, carious teeth, dental plaque, and tonsillar crypts.[20,21] *Actinomyces* infections have an endogenous source and are infrequent in children <10 years of age, but these infections are underrecognized probably because of fastidious growth requirements.[22–28] *Actinomyces* spp. take advantage of breaches in mucosal barriers or obstruction or aspiration to become pathogenic.[20,29] Cervicofacial and oral disease is associated with trauma, dental procedures, eruption of a molar tooth, oral surgical procedures, or dental infection. Pulmonary infections usually follow aspiration of oropharyngeal or gastrointestinal secretions. Other less common routes of infection are extension from cervicofacial disease or spread from the abdomen and, rarely, dissemination through blood from other sites of infection (e.g., pelvic or orofacial). Gastrointestinal infection frequently follows loss of mucosal integrity, as can occur with appendicitis, trauma, or foreign bodies. The use of an intrauterine contraceptive device is linked to the development of actinomycosis of the female genital tract.

Actinomyces infections are uncommon and indolent, but invasive. Infection generally is polymicrobial and can involve any body organ,[30] including the heart. Other copathogens with *Actinomyces* act synergistically by enhancing the spread of infection through inhibition of host defenses and reduction of local oxygen tension. The diagnosis often is delayed because of nonspecific and prolonged symptoms.[31] Patients with chronic granulomatous disease have an unusual susceptibility to *Actinomyces*.[32] Two cases of cutaneous actinomycosis have been associated with anti–tumor necrosis factor-α therapy.[33]

Clinical Manifestations

Unique characteristics of actinomycosis are indolent inflammation with spreading (“burrowing”) through soft and bony tissue planes to contiguous sites or along fascial planes to remarkably distant sites. The hallmark of actinomycosis is spread that fails to respect tissue planes. Classically, small abscesses form at the site of origin, with extension to form multiple sinus tracts that can drain yellow, gritty, purulent material (sulfur granules) composed of spheroid colonies of radiating club-shaped filaments, neutrophils, debris, and granulomatous reaction. *Actinomyces* grows in tissues in microscopic or macroscopic clusters of tangled filaments surrounded by neutrophils. The differential diagnosis includes other chronic infections at these sites, including tuberculosis, nocardiosis, and complications of foreign bodies. The most common sites of infection are cervicofacial, abdominopelvic, thoracic, and central nervous system.

Cervicofacial Actinomycosis

Most infections in immunocompetent people are cervicofacial. Depending on the composition of the concomitant synergistic flora, the onset can be acute, subacute, or chronic. The most commonly recognized manifestations are “lumpy jaw,” which is either a slowly enlarging, fluctuant, painless swelling over the lower border of the mandible or a widely spread infection that involves the submandibular area; or osteomyelitis of the mandible or maxilla. Infection spreads slowly, and draining fistulas can occur (usually to the mucosal side) and can be accompanied by trismus.[23,24] Fever or systemic illness usually is absent. Chronic tonsillitis, dental decay, mastoiditis, and otitis media are risk factors, but some patients have no recognizable disorder or preceding event. Periostitis or osteomyelitis can develop if the infection extends to the facial and maxillary bones (or rarely can complicate a primary disorder of bone such as fibrous dysplasia) (see Fig. 78.6). Primary infection can develop in the palate, scalp, salivary glands, maxilla, paranasal sinuses, tongue, larynx, hypopharynx, trachea, and neck.[34,35] Meningitis also can occur if the process extends through sinus tracts into the cranial bones.[36] The prognosis for soft tissue infections is excellent with extremely prolonged antimicrobial therapy (sometimes >1 year), frequently without surgical intervention. In a review of 19 cases of actinomycosis presenting as osteomyelitis in children, however, the mandible was most commonly affected, age was predominantly young school age, only one half had a predisposing factor, and patients with mandibular cases required >1 debridement procedure for cure.[37]

Abdominal and Pelvic Actinomycosis

The appendix is the most frequent gastrointestinal site. Appendicitis with perforation is the most common predisposing event; unrecognized foreign body perforation (e.g., needle, pin) also has occurred. The inciting event can precede the diagnosis by months to years. Chronic nonspecific symptoms consisting of fever, chills, weight loss, diarrhea or constipation, abdominal pain, and night sweats, with few abdominal symptoms, are typical and can mimic tuberculosis or lymphoreticular malignant disease. Infection can spread to other intra-abdominal (e.g., hepatic) and pelvic viscera. Primary pelvic infection can complicate abortion, retained surgical suture, intrauterine device endometritis, tubo-ovarian abscess, or pelvic inflammatory disease.[38] Patients can have an indolent vaginal discharge, abdominal or pelvic pain, menorrhagia, fever, and weight loss.

Thoracic Actinomycosis

Thoracic actinomycosis usually starts as undetected aspiration pneumonia in a predisposed host (Fig. 195.1). Neurologically impaired children, who frequently aspirate and also have poor dentition, account for some of these cases. In a review of thoracic actinomycosis in 55 children, however, only 5 (9%) children had this risk factor.[31] Chronic indolent and slowly progressing pneumonia with or without pleural involvement is the most common manifestation. Tachypnea, chest pain, and productive cough are not prominent. Fever and weight loss can be the only manifestations. A high index of suspicion is required. Infection typically burrows through ribs (to cause an osteolytic lesion) and can manifest as a subcutaneous mass on the thorax with or without a draining sinus,[19,26] so called *empyema necessitans*.[39] Infection can mimic malignant disease, tuberculosis, and lung abscess. Thoracic infection can traverse tissue planes or can follow fascial planes to the soft tissues of distal extremities or through the diaphragm into the abdomen.[40]

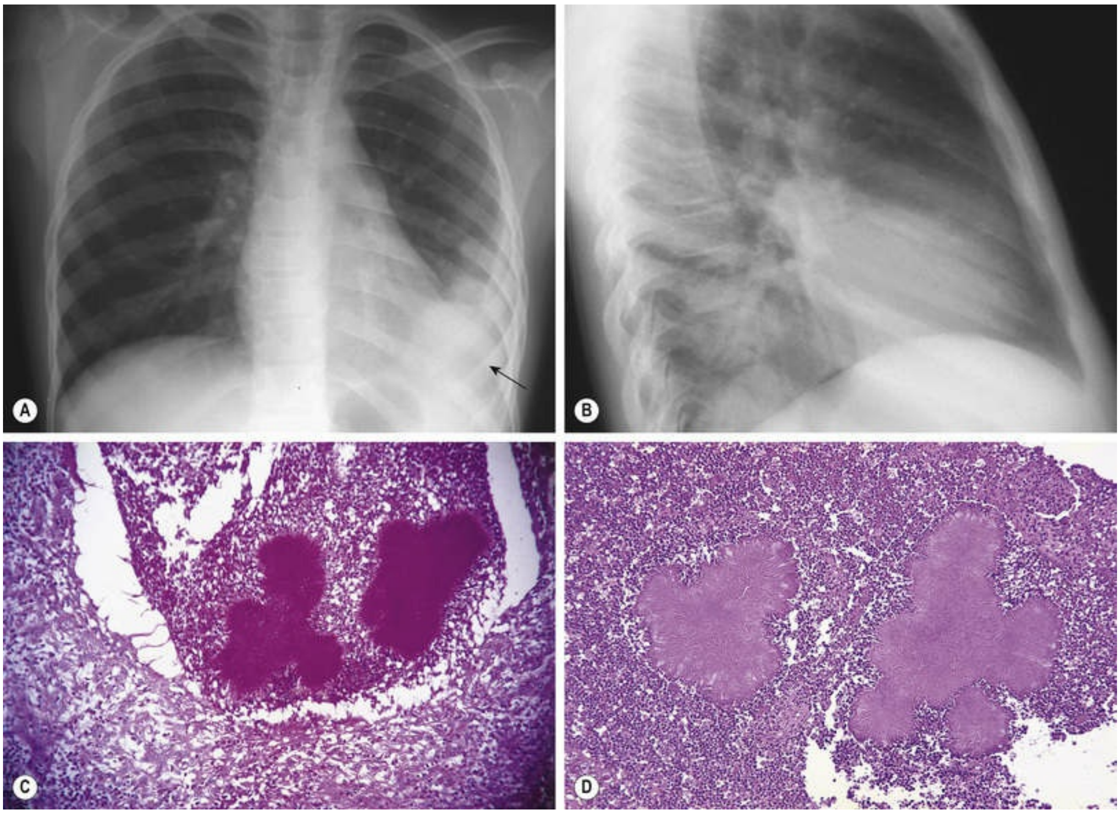

FIGURE 195.1 **Thoracic actinomycosis. A 9-year-old girl had a lump noted on her lateral chest wall. She was afebrile, had no respiratory**

tract complaints or abnormal findings except a nodular mass on the 10th rib anteriorly. She had a history of left lower lobe pneumonia and atelectasis 8 months earlier. (A and B) Chest radiographs show left lower lobe pneumonia, loculated pleural collection, and a lytic lesion of the rib (*arrow* in A). Biopsy of the rib lesion stained by (C) periodic acid–Schiff and (D) hematoxylin and eosin show histologic findings of chronic osteomyelitis and sulfur granules. Culture of specimens from lung, pleura, and rib yielded growth of *Aggregatibacter actinomycetemcomitans* and *Actinomyces israelii.* (Case courtesy of D. V. Schidlow and E. N. Faerber, St. Christopher's Hospital for Children, Philadelphia, Pa.)

Diagnosis and Treatment

The diagnosis of actinomycosis often is delayed because of its subacute clinical course and the frequent lack of inflammatory symptoms. Actinomycosis can mimic tumors, tuberculosis, nocardiosis, or fungal infections. Histologic identification of sulfur granules is pathognomonic but is not a universal finding. Gram and acid-fast stains are helpful in differentiating probable *Actinomyces*. Isolation of organisms is extremely important to confirm the diagnosis. Immediate transport of clinical specimens in anaerobic media is required.[39] Matrix-assisted laser desorption/ionization–time of flight (MALDI-TOF) spectrometry is useful for rapid identification.[16] Molecular methods, including 16S rRNA gene sequencing, aid accurate identification.[20] Frequently, a less fastidious copathogen, *Aggregatibacter actinomycetemcomitans*, is the sole isolate and predicts the presence of *Actinomyces*.[23,24,40] A singular role of *Aggregatibacter* is possible, and some patients have responded poorly to therapy when clindamycin, erythromycin, or vancomycin was used (to which *Aggregatibacter* but not *Actinomyces* is resistant).[30,40] Prolonged antimicrobial therapy is the cornerstone of treatment. Usually, cervicofacial infection responds to antibiotics alone. Drainage of large thoracic, abdominal, or soft tissue abscesses, extensive resection of affected tissues, and excision of sinus tracts generally are required. *Actinomyces* and *Aggregatibacter* are exquisitely susceptible to penicillin and extended-spectrum penicillins. *Actinomyces* is susceptible in vitro to a wide range of β-lactam agents, and these drugs, combined with a β-lactamase inhibiting agent, are regarded as agents of first choice when polymicrobial infection is likely.[16] The duration of therapy is more important than the route of administration. Initially, aqueous penicillin G can be used intravenously (depending on the patient's clinical status), followed by 6 to 12 months of oral penicillin or amoxicillin, with or without probenecid. Success is reported with shorter and oral-only antibiotic regimens.[16]

Other Gram-Positive Bacilli

Other gram-positive anaerobic bacilli include *Lactobacillus*, *Bifidobacterium*, and *Eubacterium* species. These genera are part of the normal flora of the female genital tract, oral cavity, and gastrointestinal tract.[40] Polymicrobial infection usually occurs at contiguous body sites (e.g., periodontal disease and infections of the female genital tract and abdominal viscera). Rarely, bloodstream infection also can occur. Most *Bifidobacterium* isolates are recovered from specimens from patients with chronic otitis media, abscesses, peritonitis, aspiration pneumonia, and paronychia. Most *Eubacterium* isolates are associated with abscesses, peritonitis, decubitus ulcers, and bite wound infections. *Lactobacillus* is recovered mainly from abscesses, aspiration pneumonia, bloodstream infection, and conjunctivitis.[40] Predisposing conditions are previous surgical procedures, malignant disease, corticosteroid therapy, and immunodeficiency. These genera usually are susceptible to penicillins, carbapenems, and clindamycin. However, *Lactobacillus*, some *Eubacterium*, and other facultative anaerobes are resistant to nitroimidazoles. Cephalosporins, erythromycin, and tetracycline have variable activity.

Key Points

Actinomyces Species

Description

- Filamentous branching gram-positive catalase-negative bacillus
- Anaerobic or microaerophilic growth in vitro
- *Actinomyces israelii* the predominant species causing disease

Epidemiology

- Colonizes human oral cavity early in childhood
- Normal flora of mouth, gastrointestinal, and female genital tracts
- Attains access to tissue through a breach in mucous membranes (i.e., following trauma) or by aspiration
- Infections usually polymicrobial
- Special hosts at risk: patients with chronic granulomatous disease

Clinical Features

- Infections are indolent.
- Diagnosis often is delayed.
- Hallmark is spread that fails to respect tissue planes.
- Development of sinus tracts also is characteristic.
- Most common sites of infection:

▪ Cervicofacial (normal hosts)

▪ Abdominopelvic

▪ Thoracic

▪ Central nervous system

Diagnosis and Treatment

- “Sulfur granules” (clumps of microorganisms in vivo) can be seen.
- Bacteriologic identification confirms diagnosis
- Prolonged antimicrobial therapy is key to successful treatment.

- Penicillins, clindamycin, cephalosporins all are active.

Description of the Pathogen

Mycoplasma pneumoniae is a member of the class Mollicutes, which includes bacterial pathogens and commensals found in many animals and plants. These pathogens comprise the smallest self-replicating prokaryotes known to cause infection in humans.[1] *M. pneumoniae* is approximately 120 to 150 nm, about the size of myxoviruses, and it passes easily through membrane filters intended to prevent bacterial contamination. Humans are the only known natural hosts for *M. pneumoniae*.

The absence of a cell wall distinguishes *Mycoplasma* from other pathogenic bacteria and results in the following additional characteristics: (1) growth on cell-free media only if sterols and other nutrients are provided by yeast extract and animal serum; (2) pleomorphism, preventing classification as either cocci or bacilli in the manner of conventional eubacteria, and variable ability to take up bacteriologic dyes such as Gram stain; (3) resistance to penicillins and cephalosporins, which act by inhibiting cell wall synthesis; and (4) susceptibility to desiccation, a factor that mandates proper handling of clinical specimens for culture and explains close contact as a means of person-to-person transmission.

Pathogenesis

M. pneumoniae gains access to the respiratory tract through aerosolized droplets spread among close contacts. Specific attachment to the respiratory epithelial tissue occurs primarily through interaction between a host epithelial cell receptor and the organism's P1 attachment protein, a 169-kd surface antigen.[2–4] Other structures that participate in cytadherence have been identified.[5] Following attachment, hydrogen peroxide and superoxide radicals synthesized by *M. pneumoniae* act in concert with endogenous toxic oxygen molecules generated by host cells to induce oxidative stress in the respiratory epithelium.[6] Once *M. pneumoniae* reaches the lower respiratory tract, the organism may be opsonized by complement or antibodies. Activated macrophages begin phagocytosis and undergo chemotactic migration to the site of infection. $CD4^+$ T lymphocytes, B lymphocytes, and plasma cells infiltrate the lung. Further amplification of the immune response occurs in association with lymphocyte proliferation, production of immunoglobulins, and release of tumor necrosis factor-α, interferon-γ, and various interleukins.[7] Lymphocyte activation and cytokine production either can minimize disease by controlling infection or exacerbate disease by stimulating immune-mediated lung injury.

Extrapulmonary complications of *M. pneumoniae* infection can occur as a consequence of immune-mediated injury or direct invasion. *M. pneumoniae* has been identified by polymerase chain reaction (PCR) in cerebrospinal fluid (CSF)[8] and serum,[9] thus indicating that dissemination occurs in some cases. Effects of cross-reactive antibody with host tissues remain the proposed mechanisms for hemolysis and cutaneous manifestations.[10]

Epidemiology

The age at which *M. pneumoniae* should be considered among causes of lower respiratory tract infection is uncertain. Although primarily a disease of adolescents and young adults,[11–13] *M. pneumoniae* infection has been recognized as a cause of lower respiratory tract disease in young children.[14–22] In Finland, *M. pneumoniae* was the attributed cause of community-acquired pneumonia (CAP) in 9% of children 0 to 4 years of age and in 40% of children 5 to 9 years of age.[18] *M. pneumoniae* accounts for approximately 20% to 40% of cases of CAP in junior high school and high school students and for up to 50% of cases among college students and military recruits.[23–27] The incidence of endemic *M. pneumoniae* CAP ranges from 1 to 2 per 1000 children <5 years of age, 3 to 4 per 1000 children 5 to 15 years of age, and <1 per 1000 adults <70 years of age.[13,26,28]

Epidemic *M. pneumoniae* infection occurs at 3- to 7-year intervals in the United States, superimposed on low-level endemic disease.[26,29] Community epidemics can be unrecognized until clusters of extrapulmonary complications occur because testing is not performed routinely in the office setting and *M. pneumoniae* is not a publicly reportable disease.[30] Factors that facilitate the occurrence and persistence of outbreaks of *M. pneumoniae* infection in institutional and military settings include the difficulty of making a rapid diagnosis, the long incubation period (2–3 weeks), and prolonged respiratory tract shedding (weeks to months following infection).[31,32] Persistence of the organism in many cases despite antibiotic therapy contributes to protracted outbreaks.[33]

Epidemics of *M. pneumoniae* infection commonly begin in the fall and can persist for months. Young children often serve as the index case within a family; they commonly have symptoms of upper respiratory tract infection or few overt symptoms.[12] Sequential transmission to family members frequently occurs with 2- to 4-week lapses between cases; approximately 40% of family members develop infection.[11,31,33] The attack rate is approximately 25% in other closed populations, including nursing homes.[27,34] Smoking appears to modify the risk of infection. During an epidemic among military trainees, preexisting immunoglobulin G (IgG) anti–*M. pneumoniae* was protective in nonsmokers, with an attack rate of 30%, whereas the attack rates in antibody-positive smokers and antibody-negative nonsmokers ranged from 77% to 86%.[35] Longitudinal community surveillance and studies of military recruits demonstrate that *M. pneumoniae* infection provides at least shortterm protection from subsequent infection and that immunity after pneumonia lasts longer than that after asymptomatic infection or upper respiratory tract disease alone.[36–38] The relatively mild course of infection in very young children has led to speculation that infection in early childhood results in a sensitizing immunologic response necessary for the development of lower respiratory tract disease later in life.

Clinical Manifestations

Respiratory Tract Disease

M. pneumoniae was first isolated during efforts to determine the cause of the clinical syndrome referred to as "primary atypical pneumonia."[39] Failure of patients with this infection to respond to penicillin or sulfonamide therapy (the standard therapy for pneumococcal pneumonia) was considered "atypical."
